The necessary energy for the movement of trains was provided during the 19th century by steam-powered engines and was replaced by diesel-powered engines during the 20th century. Energy can be provided alternatively by electric traction, which was introduced in the early 1900s and proved to be an effective solution from an economic point of view for railway lines which had heavy traffic load.

The railway system has one degree of freedom, in contrast to the road system which has two degrees of freedom; thus once the direction of the train movement changes, it becomes more complicated than in the case of road vehicles, as special installations, called switches and crossings, are needed. Furthermore, the braking distance, or stopping distance, is greater for trains than it is for road vehicles, and normally needs around 1300–1400 m for a speed of 200 km/h, 7500–9000 m for a speed of 320 km/h. In order for railways to offer safety of movement, they are operated by a complicated system of signaling, which nowadays is facilitated by application of the Global Positioning System (GPS) and Intelligent Systems.

As is the case with any technical system, railways require regular maintenance to run properly and accurately. However, if railways are to offer a non-stop service, the maintenance of railway infrastructure is supposed to be conducted either during the intervals between successive trains or during night hours, under extremely difficult conditions.

Effective management of railways is based on an optimal synergy of all components of the railway system, track electrification (or other power providing technique)—signaling, a really heavy and rigid system. However, as for many decades, the operation of railways was under state control, it was ascertained that railway legislation and particularly labor legislation protected the rights of all working parties within the sector, rendering the whole situation rather inflexible and difficult to change.

As railways have been developed within the context of national interests and regulations, they present numerous differences regarding track gauge, electrification and signaling systems, loading gauge, axle load, etc. A remedy to tackle this problem is interoperability, that is, the ability of the rail system to allow safe and uninterrupted operation of trains and assure a specific level of performance. Interoperability refers to technical, commercial, and legal issues and should be among the first priorities of railway managers.

Railways: Engineering Oriented or Customer Oriented

Transport is not an end in itself, but only a means to satisfy other human needs such as work, leisure, provision of goods at the right place and time. Railways have been operating for decades under quasi-monopolistic conditions and put more emphasis on technological and engineering aspects and less on commercial ones. Thus, when competition was introduced in the transport

Figure 1 The internal and external environment of railways. *Source: Modified by Profillidis (2016).*

and recently within the rail sector, it proved difficult to convince railway staff that engineering was not their priority but rather the satisfaction of consumers' needs by offering lower tariffs, reduced travel times, increased quality of service, while claiming less or no funding from the state (in the form of subsidies), so as to survive in an extremely competitive environment.

Understanding a Constantly Changing World

The Internal and External Environment of Railways

A fundamental prerequisite for any form of management is to understand anything surrounding the activity under study (i.e., in our case, railways), that is all the entities that can affect directly or indirectly the specific activity. All these entities constitute the environment of railways. We often distinguish between the internal and the external environment of a company or an entity. The internal environment comprises all the components of a company (e.g., employees, climate within the company, management, etc.) as well as all interactions with its competitors, whereas the external environment refers to the outside factors or even conditions (e.g., societal changes, shift in regulatory issues, etc.) that could somehow have an impact on it. The external environment can be further subdivided into: the micro-external (or organizational external) one, which includes all the factors that impact directly the operation of a company and the macro- external (or general external) one, which includes all the factors that a company finds quite impossible to control.

Fig. 1 illustrates the various factors of the internal and external environment of railways. The success of any form of organization and management of railways depends on the ability to adapt to the changing situations of the internal and external environment.

A Systems Approach for Railways

Effective management of railways aims to provide the best synergy of all railway components described previously, on the one hand, and on the other hand to react to all factors that are related to the environment of railways. Such a synergy cannot be ensured, unless railways are considered as a system; for that reason, the management of any railway entity should be considered within a systems approach, which usually has the following successive steps: definition of the problem, targets to be met, evaluation criteria, alternative solutions, legislation and external constraints, environmental constraints, priorities and criteria of evaluation, assessment of alternative solutions and choice of the best one, application, problems during application, and finally evaluation of results.

Lifestyle, Environmental Sensitivity, Artificial Intelligence, and Management of Railways

Lifestyle as a synthesis of concepts, interests, opinions, and behavioral orientations is always a crucial factor that should be carefully studied before any managerial decision is made. Among those characteristics that permeate lifestyle in the 2020s are the following: increasing individualism, mimesis and expanding domination of the image over thinking and rationality.

Both the increase of environmental sensitivity and the urgent need and call for reduction of CO₂ emissions can prove powerful tools in the hands of railway managers, particularly in commercial and tariff policies, to attract new demand or stabilize existing demand.

Our way of thinking and acting is revolutionized by artificial intelligence (AI), which is the science of making machines or systems doing things that would otherwise require human intelligence. Some essential features of AI systems are that they are programmed to think like people, to act like people, and to think rationally and reasonably (to the extent that it is possible based on

the programming performed). Applications of AI in railway management can simplify procedures, facilitate decision-making aspects and replace routine staff (Engelbrecht, 2007).

Understanding the Transport and Rail Market

An Oligopolistic Transport Market

Railways coexist and compete in the transport market with other transport modes: private cars (for short distances), buses (for short and medium distances), airplanes (for distances longer than 500 km). The transport market has clearly the characteristics of oligopoly: a small number of large companies tend to dominate the market by controlling most of the transportation of people and goods and thus gaining the profits rendered from this activity. It is noteworthy that these companies are strongly interdependent in terms of their pricing and commercial policies. For example, if for any reason airlines serving the London-Paris route modify their airfare prices, the operating company of high-speed trains (i.e., Eurostar) has to modify inevitably its ticket pricing so as to be quite competitive. Interdependence in the transport market is a key characteristic for railway management and this form of competition is often called inter-modal competition.

The Railway Market: From Monopoly to Competition

With regard to the railway market, depending on the orientations of the economic policy of each state, we can witness many forms of organization which can range from monopoly to full competition, often referred to as intra-modal competition.

In a monopolistic railway market, such as the one operated in China, there is only one provider of railway services who dominates the market and sets tariffs. As in most cases, the only provider of railway services is owned by the state and thus the only form of control is the state.

In a fully competitive railway market, such as the one in the United States, there are many providers of railway services who are quite competitive in the market and offer tariffs and conditions of services without any kind of control exercised by the state. Regulation is at a low level and refers particularly to issues related to safety and financial solvency of railway companies operating in the market.

Within the range between monopoly and full competition, there are many forms of partial competition, such as in the European Union; full competition in some sectors, for example, international railway freight, monopoly in other sectors, for example, domestic railway passenger transport (also known as “cabotage” rights).

A Unified or Separated Railway

Before introducing any kind of competition within the railway market, railway managers should respond to a crucial question regarding the structure of railways: will they continue to keep the old structure of railways unchanged, by controlling both infrastructure and operation, or will they decide to separate the infrastructure from the operation of railways? In the early 1990s particularly in Europe, there was a strong belief that it would be difficult to introduce competition in the railway sector if the old organization of railways was kept unchanged, that is if the same company was responsible for the railway infrastructure and operation. In this line of thinking, the separation of railway infrastructure from operation was seen as a first (and inevitable) step towards introducing competition in the railway sector. In the separated form of railways, many rail operators can run on the same infrastructure by paying appropriate charges in relation to the quality of railway infrastructure (values of maximum speed, axle load, electrification or not, etc.), the time (slot) of the journey, the distance traveled, etc. However, there should not be any kind of discrimination in favor of existing state-owned operators and against new entrants.

This European conception of separating infrastructure from operation as a prerequisite for competition is not considered universally acceptable. Thus, in the United States, Japan, Canada, and elsewhere, one rail operator owns the infrastructure and operates services, while permitting other rail operators to run on that infrastructure by paying appropriate charges and competing with the owner of that operating company.

Separation of infrastructure from operation can take place in many shapes and forms, the most common being the following:

- Accounting separation: Both infrastructure and operation are part of the same company, but accounts of infrastructure are separated from those of operation. Accounting separation can be more detailed if the whole railway activity is separated in more business units such as infrastructure, electrification, signaling, operation of passengers, operation of freight, maintenance of rolling stock.
- Institutional separation: Infrastructure and operation are legally different companies without any form of legal interdependence.
- Within a holding company: Infrastructure and operation are different companies, but not totally independent, as they are part of a holding company with a common board and chairman.

The unified model of railways is in congruence with a more interventionist state policy, whereas the separated one is closer to state policies favoring competition. Separation or not is not a purpose in itself, but only a tool to achieve the most effective railway, offering a high level of services (such as reduced travel times, appealing prices, easiness, etc.) to clients, higher productivity and revenues to the company, increased levels of safety and security, lower state subsidies, satisfactory salaries for the personnel. The decision of railway managers to separate or not the unified railway should be based on such criteria and not on ideological or political prejudices.

Public or Private Railways

It is noteworthy that the ownership of a company (depending on the management policy) does not directly affect neither the market nor the consumer (or client). What matters is the existence of healthy competition or its absence. As the state usually fails to establish a real competitive market, it often presents partial privatization or full sale of railways as a condition for competition; this usually turns out to be a policy error or an illusion.

The privatization of railways often follows the path set by the privatization in other sectors such as telecommunications, airways, etc. This approach suggests that railways should be treated in the same way as profit making businesses by overlooking the complex character of the railway system and that most activities of railways are loss making. One would expect that a privatized railway would increase productivity and quality of services offered to the clients and attract private funding for the necessary modernization. However, it seems that common practice fails to meet the expectations set.

Failure to undertake the necessary changes, once privatization of a railway company has been realized, seems to have as origin the fact that railways have low margins of profitability and only in some sectors of freight and long-distance (particular high-speed ones) passenger transport. Introduction of modern management in a private railway can improve indices of finances and productivity but cannot overturn the situation from a heavily loss making activity to a profit making business. Indeed this is the case for the privatization of infrastructure, if safety continues to be a top priority upon privatization.

Throughout the world, successful and unsuccessful examples of privatizing railways have come to light. British railways tried to privatize their railway infrastructure in 1995 but were obliged to renationalize it in 2003. Passenger and freight activities of railways in the United Kingdom were allocated to a number of private companies, each one monopolizing specific routes. Government support per passenger-kilometer was (according to the British Office for Rail and Road) 0.04€–0.08€ between 1990 and 1995 and increased to 0.08€–0.17€ between 2005 and 2018 (all values of year 2018). Countries such as New Zealand and Estonia were obliged to renationalize their railways after an unsuccessful privatization. On the other hand, privatization of railways was more successful in the United States, Canada, Australia, and Japan, to mention a few.

To overcome any eventualities, railway managers should proceed with caution once considering privatization and focus on some categories of freight (bulk volumes, combined transport), some local passenger services (for which sufficient public service obligations are provided) and high-speed services.

Managing Finances of the Rail Activity

The Revenues/Expenses Ratio

Revenues of unified railways have as principal sources the tariffs paid by clients (passengers and/or freight) and state subsidies (provided usually only for passenger services). In the separated form of railways, revenues of the infrastructure manager are fees paid by operating companies for the use of infrastructure and state subsidies. A marginal part of revenues can come from fees of advertising companies. The expenses made by railways are principally related to paying personnel, energy and materials, and interests that concern the service of past loans.

The revenues-expenses ratio clarifies the ability of a rail company to survive (if it is higher than 1.0) or not. Successive years with revenues/expenses ratios lower than 1.0 will oblige managers either to borrow (if the market considers they possess some financial solvency) or be absorbed by another company (if some comparative advantages of the company in difficulty are essential for the purchasing company) or to declare bankruptcy.

A Good Understanding of Costs and Yields

Any managerial activity is an attempt to establish equilibrium between costs and revenues. Railways can reduce their costs by replacing labor intensive activities with computers and machines, by increasing productivity and outsourcing some railway activities (e.g., cleaning of trains).

Parallel to controlling costs, railway managers should try to increase yields, that is, unit revenues. This can be only achieved if railways have some kind of monopolistic or competitive activity; otherwise, any increase of yields risks shifting railway traffic to competitors, in relation to the values of price and cross elasticities. Railway yields were in the mid-2010s as follows:

- For passenger transport, in international US\$ per p-km: 0.18–0.25 for Western Europe, 0.10 for Eastern Europe, 0.3 for the United States, 0.15 for Japan.
- For freight transport, in international US\$ per t-km: 0.06 for Western Europe, 0.08 for Eastern Europe, 0.025 for the United States.

Increase of Productivity

Productivity reflects the rates of a production activity and is the outcome of a combination of several factors: labor, equipment, etc. We usually use as index of railway productivity the labor productivity, that is, the output volume of traffic to the total number of employees; this is expressed in traffic units of passenger-kilometers + ton-kilometers per employee. Indicatively in 2018, on a worldwide scale, average railway productivity was 2 million passenger-kilometers + ton-kilometers per employee.

High railway productivity is the result of a number of factors, and as such we could isolate high traveled distance, appropriate number of employees, use of modern equipment, effective management, strong competition in a specific market, and motivation of staff.

A Segmentation of Traffic

As railway traffic is extremely heterogeneous, it is practically impossible for managers to know which segments contribute profits and which ones make losses (and to what degree). For this reason, railway traffic is usually segmented as follows:

- Passenger traffic: Commuting (it serves the suburbs of a city and is strongly subsidized), regional (it serves regional centers), intercity (it serves major population centers), high-speed,
- Freight traffic: Small isolated parcels, bulk freight (minerals, grains, coal), general merchandise (products sold in supermarkets), express and urgent freight.

Financial indicators should be provided for each of the above segments of the market. Thus, railway managers can decide in which segments of the market have an interest to remain and which segments to discard.

Planning the Railway Activity

Planning As an Essential Prerequisite for Management

The only way to ensure consistency and compatibility between goals and results to a complex activity is to have a plan for this activity, that is, set goals, define actions to be performed, estimate and allocate resources, determine stages of application and deadlines, identify responsibilities of actions, define mechanisms of monitoring and evaluation. Planning is the management of change and should be characterized by consistency, flexibility, and adaptability.

Business Plans and Master Plans

Everyday management should be integrated in a general context of planning so as to avoid improvised and unprepared actions. To achieve this, essential tools for any railway manager are Business Plans and Master Plans. Whereas a Business Plan emphasizes more on organizational, economic, financial and investment aspects, a Master Plan refers to the whole of the railway activity and includes more details on technical equipment and projects. A Business Plan is a guide and a frame of action and not an implementation program and it contains analysis of the following (UIC, 2008):

- position and share of railways in the transport market,
- financial analysis, revenues and expenses, costs and tariffs, comparative analysis with other transport modes,
- weaknesses of the present organization and management,
- proposal of a new strategy with clear targets, quantification and forecast for the evolution of the fundamental indices of the railway activity, such as passenger and freight traffic, revenues, expenses, cash flow, productivity,
- new investment required, sources of financing, expected return of investment, volume of loans,
- sensitivity analysis for all forecasts, risk analysis.

Project Management: a Necessary Tool for Most Railway Projects

Railway projects are complex, include many heterogeneous components (e.g., signaling, rails, ballast, etc.), and take time to be materialized. In order to execute a railway project successfully, that is to follow up and respect the initial budget, partial and final deadlines and quality of work, effective management is necessary and is known as project management.

Project management consists in directing and administrating a complex project (by breaking it down in smaller components) and is in principle a science but to a certain degree an art. Project management can be executed by in-house staff or by outside consultants. It usually comprises four discrete stages: organization (requirements, accurate definition and description of the project, constraints, costs, programming of works, allocation of resources, funding), development (standards, studies, alternative strategies, more accurate programming of schedules), setting up (quality assurance and procurement plan, organization of site management, calculation of quantities of materials and man-hours of staff, invitation to tenders), execution (control of materials and quality of work, security measures and medical facilities, progress reports, measurement of works done and payments, test runs, recording of data of the project, certification to deliver the project for use).

Some cases of rail projects that require project management are: construction of a new high-speed line, track upgrading, electrification of a line, signaling and safety installations, a new tunnel or bridge, a marshalling yard, a railway station.

Figure 2 Values of infrastructure charges for the operation of passenger trains in European countries in 2016. Source: *European Commission (2019)*.

Management of Railway Infrastructure

Deciding Efficient Values of Infrastructure Charges

Management of infrastructure aims at ensuring safe operation of passenger and freight trains at the scheduled speed, with a high quality of transport, at the lowest possible cost. Costs of infrastructure refer to costs of maintenance and operation of track, electrification equipment and signaling equipment, and also to management of rail traffic. In the monolithic organization of railways (when a company owns both infrastructure and operation) expenses of infrastructure are covered from charges paid by other operators running on the track, eventual public subsidies and a part of revenues of the company from the operation of passenger and freight trains (cross subsidies). In the separated organization, expenses of infrastructure are covered from charges paid by operators and eventual public subsidies.

Thus, the level of infrastructure charges is a critical decision of infrastructure management: low charges favor operators' finances but burden the infrastructure's finances, whereas high charges favor the infrastructure's finances but burden the finances of operators. The following figures illustrate certain values of infrastructure charges for the operation of passenger and freight trains in European countries. Average values of charges are 1–3 €/train-km for passenger trains and 2–4 €/train-km for freight trains (Figs. 2 and 3).

Level of Outsourcing

In order to balance revenues and costs, railway managers are obliged to reduce their costs. As 40%–60% of infrastructure charges are personnel salaries, it is often preferable to outsource a number of infrastructure activities (principally maintenance works), usually through a bidding procedure.

Condition-Based Maintenance

In the past, infrastructure managers had to opt for maintenance strategies of the track and the rolling stock among the following alternatives:

- planned maintenance: It follows predefined scheduled intervals with no consideration about the best time for maintenance,
- preventive maintenance: Based on regular monitoring of each component of the track and the rolling stock but also on previous experience, a maintenance schedule is defined. It does not ensure that the specific railway component under maintenance or replacement has attained its ultimate strength or operational possibilities,
- corrective maintenance: When failure of a railway component is eminent, maintenance works are undertaken. It is expensive, not optimal and a quite risky method.

Contrary to the previously mentioned strategies, condition-based maintenance aims at conducting the maintenance at the moment that is needed, that is, neither earlier nor later than the appropriate time. It is based on a continuous monitoring of the status of a railway component thanks to monitoring devices appropriately located and an immediate transmission of data to decision making centers. Thus, condition-based maintenance can be facilitated with the help of the internet of things and artificial

Figure 3 Values of infrastructure charges for the operation of freight trains in European countries in 2016. Source: *European Commission (2019)*.

intelligence: cloud data with the help of mobile mapping systems permit to transpose field records in accurate figures and design of the accurate position of the component under study, compare with the situation considered as critical and optimize the preventive maintenance plan.

Management of Passenger Traffic

Competition From Other Modes

Rail passenger traffic faces competition from other modes as follows (*Profillidis and Botzoris, 2018*):

- *Urban and commuting* traffic. It serves the suburbs of a city. Principal competitors of railways are buses and private cars. Comparative advantages of railways are reliability (as they are not affected by road traffic congestion), better travel times, lower values of ticket prices, easiness and possibility to exploit productively travel time. However, in some cases low quality of transport has been noted among the passengers' complaints,
- *Regional* traffic. It serves regional centers. As with commuting traffic, principal competitors of railways are buses and private cars. Due to a number of stops that regional trains make, private cars may provide lower travel times, in addition to an uninterrupted door-to-door travel,
- *Intercity* traffic. It serves major population and economic centers distanced some hundreds of kilometers among them. Due to high travel times, there is less competition in this case from buses and private cars, but railways may face competition from airplanes. Quality of rail services is in this case more critical than in the previous ones. A specific case of intercity traffic is *high-speed* traffic, offering rail speeds higher than 200 km/h and up to 350 km/h.

Monitoring of Passengers' Exigencies

The only way for railway managers to have an accurate estimate of their customers' characteristics, preferences, degree of satisfaction or annoyance, desired changes etc. is to conduct regularly (e.g., all 6 months) market surveys, which are usually realized with the completion of questionnaires either by the passengers themselves or by the staff of the company (in some cases by outside interviewers). Beside the determination of the profile and characteristics of passengers, market surveys can monitor assessment of passengers' choices for the services already rendered to them (revealed preference surveys) or record intentions of passengers regarding changes in rail services to be offered to them (stated preference surveys).

A survey is an experimentation of the trends, attitudes or opinions of a population and is achieved by studying a very small portion (called the sample) of that population. The sample reflects just part of the truth of the population and should represent it as accurately as possible. In most rail transport surveys, a confidence level of 95% for a margin of error of 5% can be considered as satisfactory. In order to quantify attitudes, views or desires of the respondents of a survey, some form of scale can be used (like the 5-point or 7-point Likert scale) and thus the relative degree of satisfaction of respondents can be approached. Questions of a survey refer to the following: purpose of traveling, degree of satisfaction, assessment of services and facilities in the train and the station, reasons that deter passengers from choosing traveling by train, ease of preparing the trip, transport mode to access the railway station, and frequency of traveling by train.

Railway managers should carefully examine respondents' intentions about future attitudes related to new railway services or changes in existing services. Not all positive positions should be taken for granted. It has been found that in many cases respondents were very enthusiastic about the idea of a new railway service; nevertheless when this was realized, they changed their mind and only a percentage of them realized their initial intention to use the new service. In a number of cases, market surveys are followed by advertising campaigns, as part of promoting new services or products to the public in general or to specific segments of the market.

Increase of Traffic or Profit

The old dilemma of all railway managers is whether they should aim at the increase of traffic or profit. Strategies aiming at the increase of traffic favor more socioeconomic factors and less finances of the railway company. Such strategies lead very often to deficits, which are covered by state subsidies. Strategies aiming at the increase of profit lead to higher unit tariffs and inevitably to the abandonment of a number of secondary lines in order to balance revenues and expenses.

Optimization of Finances

As rail operating costs are a function of distance, rail tariffs have been also calculated for many decades as a function of the distance traveled. Such an approach ignores competition from other transport modes (and in some cases from other rail operators). Indeed, the choice of a customer for a specific transport mode is based on the generalized cost of transport, which is the sum of the tariff paid by the customer and the monetary value of its travel time. Thus, the key for higher rail tariffs is to achieve competitive travel times and quality of service, in general.

For most itineraries, railways still apply a flat tariff, that is, the same tariff no matter the time of the day or the time of procurement of the ticket. A characteristic of all transport modes is that if the offered capacity (i.e., number of available seats) is not used, it is lost. In order to make the maximum profit from the capacity offered, railways introduce for some of their routes yield management techniques, which suggest a differentiation of the tariff paid as follows:

- in relation to the period of the day, the day of the week and the season of the year, by offering lower tariffs for off-peak hours,
- in relation to the time of procurement of the ticket: the earlier the ticket is purchased, the higher the offered tariff reduction.

Advantages for Frequent Travelers and Targeted Segments of the Market

Many companies tend to reward loyal clients. Railways should also introduce similar measures. For itineraries with a low load factor, instead of having vacant seats, railways could offer these seats at zero cost or at the marginal cost for passengers using frequently the railway services, at very reduced cost for the seniors or young, at advantageous costs for families and groups.

Effects of Elasticities

No managerial decision should be made without a thorough consideration of the values of the various elasticities, such as price elasticity (with a mean value for railways of around -0.6), income elasticity (with a mean value for railways of around 0.8), and cross elasticities of railways in relation to other transport modes (e.g., cross elasticity of rail transport with regard to the cost of use of private car has in Western Europe values around 0.20 – 0.25).

Considering Options for Door-To-Door Transport

A principal handicap of rail transport is that it does not provide door-to-door accessibility. A railway trip is just a component of a more complex procedure to assure door-to-door mobility and requires the services of bus and metro systems or of private cars and taxis or of bicycles. Some railway companies include in the price of a rail ticket the possibility to use certain free of charge services such as bus, metro, shuttle buses or bicycles at the beginning and the end of a rail trip. Thus, railways can integrate rail transport within the concept of seamless transport.

Management of Freight Traffic

Focus on Products Suitable for Railways

In the past, railways undertook any kind of freight transport, from small isolated parcels and general merchandise (for which railways are totally unsuitable compared to road transport) to bulk products and specialized freight (such as containers and chemicals) for which railways have comparative advantages, particularly regarding costs of transport. This cannot continue in a market which is becoming more and more competitive. Railway managers have strong interest in abandoning loss-making freight activities and focus essentially on bulk and specialized freight.

Increase of Average Freight Speed

Average speed of consignment of freight trains in Europe hardly exceeds 20 km/h and is far lower than an average speed of road trucks at the order of 50 km/h. This difference in average speeds is due to several reasons: delays in marshalling yards, long controls when crossing borders, a lower priority in traffic regulation for freight trains compared to passenger trains. A remedy to overcome this inherent handicap of railway freight is the creation of tracks dedicated only for freight traffic on routes with heavy freight flows. Such tracks are often called railway freight corridors and their essential technical characteristics should have a maximum speed of 120 km/h, a length of platforms of 750 m, axle loads of at least 22.5 tons, ERTMS signaling system of level 3, horizontal loading in marshaling yards. With the creation of rail freight corridors, rail freight trains can increase average speeds from the actual level (in Europe) of 20 km/h to 50 km/h or even more and ensure a punctuality of 95% (with tolerable delays at the order of 1 h).

Incorporation of Rail Freight in the Logistics Chain

Rail freight is just a component of freight transport that could be used for the transport of goods from their origin to the expected destination and should be integrated within the frame of the logistics chain, which includes in addition to the simple freight rail transport some of the following: loading, unloading, delivery, distribution, storage, flexible organization with immediate response to any kind of freight demand. Regain of rail freight competitiveness can be obtained, in addition to improvements in track and equipment, with a better organization of successive steps and a use of smart techniques in order to ensure just-in-time delivery.

The Issue of Truck Subsidiaries of Rail Freight Companies

The central inherent handicap of railways is that they cannot provide door-to-door transport, unless railway tracks reach directly the heart of industrial or production centers. But this is feasible from an economic point of view only in the case of huge industries. Thus, connection of the origin or destination of rail freight to the railway station is achieved with the use of road trucks. Railway managers should decide whether to possess a truck subsidiary (but many similar attempts like the truck subsidiary Sernam of French Railways turned to a financial disaster) or to outsource truck activities. The other alternative is to entrust road transport of freight from origin or destination to the railway station to freight forwarders, but there is the risk that rail freight managers will lose control of the market.

Summary and Conclusion

For decades, railways have been managed within a very regulatory, interventionist and state policy spirit, ignoring the situation in the market, expectancies and exigencies of clients and the amounts of money spent for them. The present analysis explains how railways can be run as a modern, open, friendly to the client, less subsidized, more commercially oriented activity. The methods presented are not uniform and have the necessary flexibility so as to adapt to the contrasting differences of the various societies and economies around the world. Competition and contestability are strong incentives for railways to modernize, together with a gradual reduction of political power upon them. Inspired from other sectors of the economy, railways can adopt some aggressive commercial and pricing strategies and revalorize their human resources.

Terminal Regulation Definition and Scope

Railway terminal regulation covers following areas:

- Physical management of terminal station (construction, maintenance, security, etc.);
- Definition terminal station access and exploitation, service pricing;
- Definition of legal status of owners and operators (state, collectivity, public, or private bodies);
- Competition rules between operators;
- Public service obligations (quantity, quality, and price of services delivered);
- Conflict prevention and solving;
- Price and access conditions to essential facilities and resources necessary for railway terminal activity (energy, land);
- Network interconnexion (technical compatibility, flow capacity).

In this broad perspective, terminal regulation is connected with railway terminal governance (who decides what), with railway terminal financing models (who pays for what), with railway terminal merchandising (how to locate railway terminal and how to manage them so as to attract passengers and clients and extract value). Railway terminal regulation also include technical regulation such as network regulation as well as security and safety norms appliance [A link to 10473: Rail network regulation can be done here], and is part of public transport regulation laws (international, national, metropolitan levels) when railway terminal is connected to intermodal nodes (buses, metro). When railway networks cross international borders, a bi- or multilateral regulation system can regulate the management of an international station and the right and duties of governments and railway companies.

This chapter is organized as follows: section “Railway Terminal Regulation Goals” introduces railway terminal regulation goals and section “Historical Background of Terminal Regulation” provides the historical background of terminal regulation. The section “Railway Diversification Reframes Terminal Regulation” explores the way terminal functional diversification goes along with a multiplication of stakeholders and a reframing of regulation conditions. Then section “Railway Market Opening in Europe and its Consequences on Terminal Regulation” details the specific but variegated conditions of terminal opening to market in European countries and section “Railway Terminal Pricing Principles in Europe” the zoning and pricing principles attached to terminal space and use. Sections “Terminal Management Charging Models Across European Countries” and “Charging Patterns for Railway Terminal Use Across European Countries” develop the terminal management charging models and their different patterns (the way terminal services are aggregated into blocks of activity across European countries), before reviewing hot topics and trends (section “Hot Topics and Future Trends in Terminal Regulation”).

Railway Terminal Regulation Goals

Following cases, railway terminal can be either railway stations related to passenger travel, either cargo terminals interesting freight or depots, interesting both. All these terminals are part of network and provide services which exploitation may lead to scarcity of resources and overexploitation. For example, traffic caused by a busy railway crossing creates lack of capacity in a freight bottleneck. Hence railway terminals are essential facilities. Cargo terminals, marshalling yards, and train depots provide the infrastructure, building, and machines for flexible and efficient railway activity and maintenance (for the notion of efficiency, see Cantos and

[Maudos, 2001](#)). Having access to a network of strategically located terminals with good connection to seaports, and offering modern rolling stock and good maintenance conditions help to reduce the time that vehicles are out of service and avoid empty trains. It secures and makes easier transshipment between rail and road or rail and sea or waterways and contribute to better flow management, which in turn leads to a reliable timetable.

Passenger railway stations are also essential facilities for transit and interurban transport. If railway activity is opened to market, stations turn into an essential facility. Railway undertakings need to have open information concerning the technical and financial conditions to access these stations, they must know how they can put a staff basis and what let services will be proposed to their final clients, the railway passengers. If railway activity is not opened to market, train flow regulation and passenger movement management are also very important to optimize the quality of railway service (train punctuality, comfort) [A link to the article 10014: Value of crowding in this Encyclopedia can be done here]. This needs also a sound regulation of the contractual relationships between station manager teams and train operator departments. Flow regulation is therefore necessary to assure fluidity in getting on and off a train, as well as to organize multimodal transport services from station to end destination. Terminal regulation is also needed in order to clarify the policy making conditions offered to nonrailway stakeholders (national governments, metropolitan governments, estate agents, data firms, etc.) in station development projects and to integrate side business activities such as shops, hotels, and other activities in stations ([Dirhaug, 2013](#)).

Historical Background of Terminal Regulation

Railway terminal regulation was necessary till the time railway lines were constructed. Even if it has changed a great deal since the 19th century, when train boomed in Europe and in the Americas, the fundamental question is still the capacity of envisioning a railway terminal as an essential facility. The genealogy of this notion is to be found at the time when various companies were obliged to find agreements in order to share infrastructural nodes, platforms, depots, carbon storage, and water for steam machines. In 1911, a conflict aroused between competing American railroad companies (respectively the Wiggins Ferry Company, the Eads Railroad bridge terminal company, and the Merchant's bridge terminal company) that were converging at Saint Louis station, one of the largest railroad centers in the world at this time. Organizing the access of such competing railroads was not a basic thing. The solution proposed was that these three independent terminal systems merged into a single system owned by 14 independent railway companies, thereby completely controlling all interconnection facilities between both sides of the river Mississippi. According to the Supreme Court, mergers of terminals into one single system avoided unnecessary duplication of facilities. However, since not all railroad companies were owners of the terminal, the Sherman Act of 1912 did require nondiscriminatory access to the merged railroad terminals. Mandatory third-party access to complementary monopolistic infrastructure led to the birth of the crucial notion of essential facility ([Dobbin, 2004](#)) ([A link with article 10006: Natural monopoly in transport can be done here]).

Railway Diversification Reframes Terminal Regulation

Most railway companies were nationalized before or after world war two in Europe, Asia, and in a majority of decolonizing countries, so terminal regulation changed a lot. Railway terminals turned to be driven by monopolistic companies and access to infrastructure was not so a problem, but large-scale railway programs (including high speed lines) were developed, along with railway modernization (e. g., line electrification). State or regional governments investments were needed for such great works. Rebuilding attractive stations and efficient terminals with public money was a part of this intent to foster rail development, seen as sustainable transport. So, terminal regulation was at this time included in the broader development of freight and passenger railway national regulation systems. Some terminals were specialized to serve port development or inland industrial plants, while urban terminals (including old depots and technical infrastructure) could be extended and redesigned into urban multifunctional programs (sometimes on an important scale). Railway terminal development schemes concerned progressively a broader array of stakeholders, including railway or metro companies, state administrations, public and private banks, municipal and metropolitan bodies, and industries. All these entities were eager to know precisely the conditions for intervening on railway land or the possibilities to buy pieces of land in terminals, and wanted to know the types of contracts (concessions, leasing, etc.), which could be signed with railway authorities for different kind of projects. Terminal regulation had to adapt and integrated new specifications. Depending on the countries, side businesses activities took place in terminal regulation schemes or were integrated in other type of regulation (land regulation, urban planning, etc.).

Japanese railway companies vertical separation and functional diversification occurred throughout the 1990s, after 1987 railway business act (which integrated «the construction of facilities around a station to promote connectivity with other transportation modes», quoted by [Fumio 2018](#), p. 395) and then after 2005 Act on Enhancement of Convenience of Urban Railways. Terminals were located in the eastern metropolitan corridor and their urban environments were exposed to the steady rise of land values, hence the railway terminal premises, tracks, technical installations, and former passenger stations were converted into dense, high rise, intermodal, and multifunctional urban centers. Many Japanese companies engaged in a wide range of side businesses, such as land development, real estate development, department stores, and mobility services. Other project interested railway corridor at the peripheries of big cities [A link to 10454: Railway station (and network) planning and management article of the Encyclopedia can be done here]. Modest train station and old tracks could be turned into new transit-oriented development schemes integrating the reconstruction of a commuting railway line, a renovated commuting station and adjacent housing programs. Regulated benefits

coming from train operation and unregulated side businesses deriving from other activities were the two dimensions of a new terminal regulation model. Each railway company was required to keep separate accounts for railway and other businesses and railway regulation was imposed only upon the railway side. Yet, according to economic cycles and to the long-term trajectory of megaprojects (in city centers) and miniprojects (in peripheral areas), railway activity, or side business activities could be more profitable, and the benefits taken from one activity could sustain the sustainability and long-term vision of the whole group.

Railway Market Opening in Europe and its Consequences on Terminal Regulation

"In theory, mixed-used developments around centrally located rail stations offer a perfect answer to the challenges of a future-oriented, post-peak oil sustainable development agenda focused on transit-accessible urban cores. In practice, however, the implementation of such megaprojects is highly complex, and costs and benefits are unevenly distributed." As Peters quote in 2012 (p. 163), Japanese terminal station megaprojects have been copied and globalized (Peters, 2009). The opening up to railway competition and the introduction of private capital in railway projects is of actuality worldwide, even in countries where a monopolistic company still dominates the national railway market. Technological companies, media and entertainment firms, real estate businesses, and hedge funds are newcomers in station (re)development projects or in railway infrastructure building or renovation. An example comes from China. Since 2014, the Chinese government launched a China railway development fund, scheduled to last for 15–20 years, with the aim of promoting private capital investments into rail projects through public–private partnerships (PPPs), in order to alleviate the debt carried by public authorities. In 2016, the Zhejiang government signed the first of such PPP agreements (34 years contract, the first four years of which for the construction, followed by 30 years of management) with the conglomerate Shanghai Fosun High Technology Group Co. Ltd. The project included land development around and above the eight new stations of the Hangzhou to Taizhou 269 km high speed line, which generated revenues could be used toward paying back railway development.

Russia and United States as well as in China and in European Union, which published, till the 1990s, various railway law packages encouraging railway market opening, historical railway companies rethink the place of terminals in their business model, and make proposition for adapting terminal regulation. Gómez-Ibáñez and De Rus (2006), and then Laurino et al. (2015) state that worldwide surveys are not numerous, the information very difficult to gather, and, moreover, both delineate with difficulty terminal economic regulation from overall railway regulation. Yet, a turning point seems to be attained. All these companies and incumbent railway undertakings understand that they have to add to the traditional tasks of terminal manager new expertises and skills, with new rules. Fig. 1 explains the value-oriented station regulation model, which associates traditional technical missions (passenger welcoming and train operation) with news targets such as passenger flow commercial fertilization and asset development. The basic

Figure 1 Value-oriented station regulation associate traditional technical missions (passenger welcoming and train operation) with news targets: flow fertilization and asset development.

role of station management bodies is still related to the maintenance of the terminal buildings, its efficient management, its development in collaboration with the urban public authority, and transport systems. But, with liberalization trend, new challenges appear when they consider their strategic role being related to the maximization of three kinds of values: land value and long-term money return to be assured in shared programs signed with public authorities (in a business to governance perspective); flow value and careful asset management guaranteed with estate, retail and digital firms (in a business to business perspective); and time value, as an element of good travel experience of railway passengers (in a client oriented approach) (Beria et al., 2012). Such a commercial repositioning includes the redefinition of terminal station owner and manager legal duties and professional capacities. Providing comfort and security, assuring cleanliness and multilingual signage, offering first and last mile innovative mobility services as well as business lounges and WIFI network is now a must in main passenger stations and it changes regulation frames, especially in European countries.

Railway Terminal Pricing Principles in Europe

Terminal regulation is affected by many ways in the general context of the opening up to competition in the European Union. The main goal of EU railroad regulation is to increase competition on the railway markets by improving the independence of stakeholders, increasing the power of regulatory bodies and guaranteeing not only regulated access to monopolistic bottleneck components, but also regulating access to rail-related services, such as maintenance facilities, terminals, stations for freight and passenger trains (Finger and Messulam, 2015).

The introduction of fair and nondiscriminating access to passenger stations, maintenance depots, and cargo terminals is presented from the 1990s onward as a necessity in order to save railway industry, which is threatened by car transport for passenger as for freight competition. Vertical separation, autonomy, and neutrality are keywords. The autonomy and responsibilities of a station manager entity must be clearly delineated in the transformation or historical companies into vertically separated entities (infrastructure manager and railway undertaking). The station manager entity has to present service neutrality. The conditions of access and use have to be published and legally guaranteed by the independent Authority in order to avoid barriers to entry for newcomers in the market. Fig. 2 shows the terminal regulation system in European Union and how public stakeholders' interactions are reorganized.

The station manager must present price neutrality toward former monopolistic railway companies and incumbent undertakings for stations, depots, maintenance units, and freight terminals access and use. Terminal zoning and terminal access charges must be defined. This means that the stations and terminals are subject to a pricing process, and a value is assigned to the use of each element of a terminal [A link with 10016: Pricing Principles in the Transport Sector of this Encyclopedia can be done here]. The price of each elements and the final price is constructed from five elements:

- The terminal position on the rail network;
- The singular nature of the location and the scarcity and value of space (urban or industrial);
- The services available at the terminal (especially intermodal services, transshipment facilities);
- The environment and amenities around the terminal;
- The possibility of capturing large flows of passengers with varying abilities to pay (in the context of a passenger station).

The pricing of a terminal is based on regulatory engineering, but also generates discussion and dialogue, with differences of opinion between the players regarding the value they ascribe to the constraints that affect the station, so the independence of regulation authority is compulsory to stabilize the criteria and make consensus on the creation of price. The notion of "reasonable profit" is included in the main charging principles laid down in Directive 2012/34/EU in this quotation: "The charge imposed for track access within service facilities referred to in point 2 of Annex II, and the supply of services in such facilities, shall not exceed the cost of providing it, plus a reasonable profit." (Article 31.7.) (...) "Where services listed in points 3 and 4 of Annex II, as additional and ancillary services, are offered by only one supplier, the charge imposed for such a service shall not exceed the cost of providing it, plus a reasonable profit." (Article 31.8.). Reasonable profit means a rate of return on own capital that takes account of the risk taken by the terminal manager in the production of the facility or service, including that to revenue, or the absence of such risk, incurred by the operator of the service facility. Such return and is in line with the average rate for the sector concerned in recent years. An external rail regulator verifies the specifications for station access, defines the implementation of the safety measures, flow conditions, intermodal services and retail development possibilities. If several operators use a terminal, the rail regulator validates the access charging system and the station pricing schemes.

Terminal Management Charging Models Across European Countries

The idea of the terminal as a natural monopoly, separated from nonnatural monopoly components, is supposed to be applied in the European countries in a similar way, with the outcome being similar. In reality, the national interpretations vary substantially and these differences are deepened by the different starting point of the national rail companies (importance of historical background and national context). Two dimensions must be taken into account.

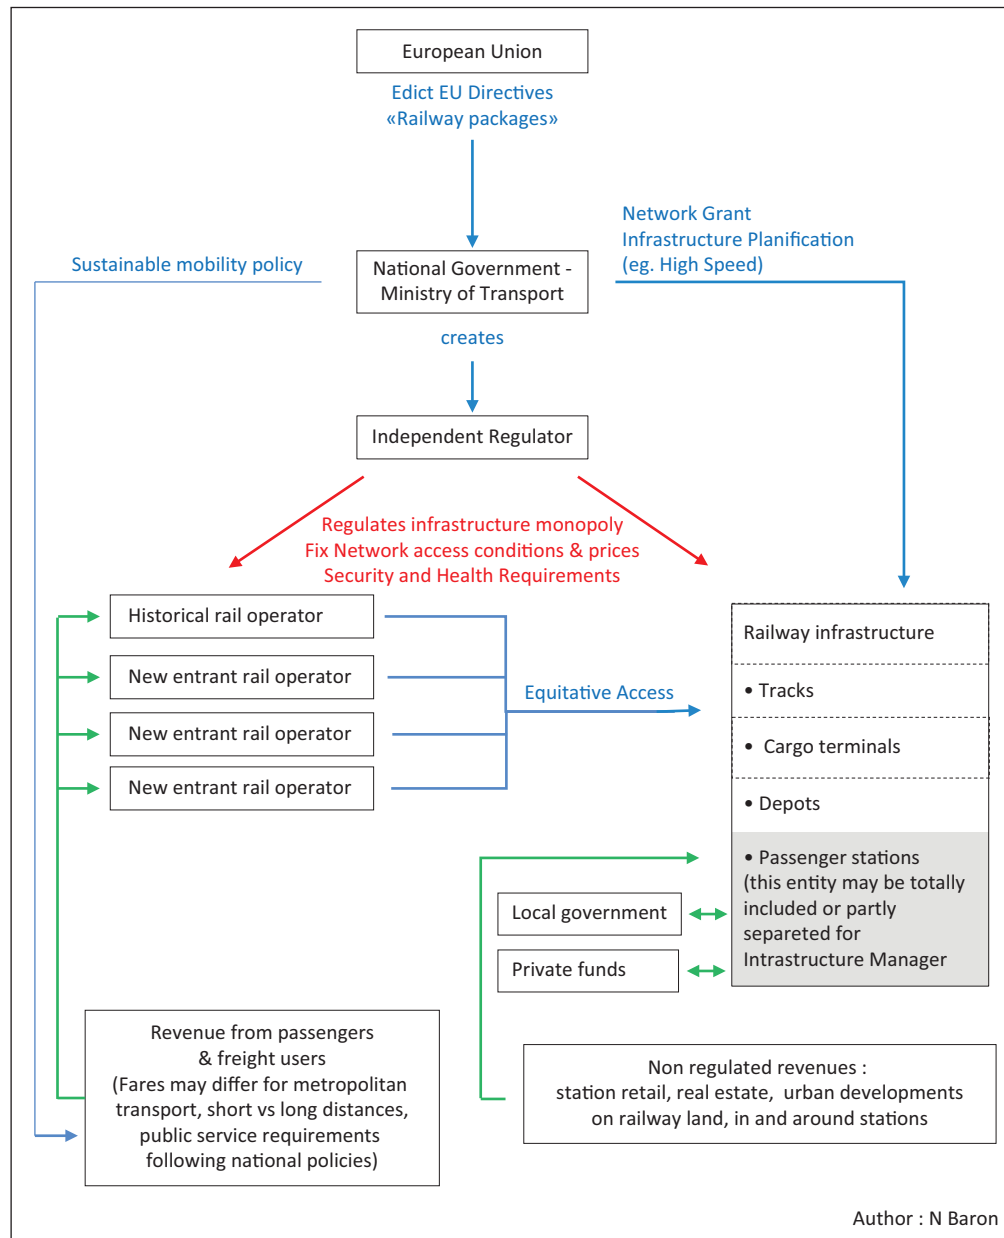

Figure 2 Terminal regulation system in European Union stakeholders interactions.

First, the way of separating railway premises ownership varies. In some countries, the ownership of depots and maintenance yards is of the incumbent, in other countries in the possession of the infrastructure manager. Thus, in Spain such facilities are not open to competitors and, in Italy, access of these facilities to competitors is subject to the incumbent's approval.

Second, the legal nature and the position of station manager entity in each national post market opening railway ecosystem differ a lot from one country to another. **Table 1** offers an overview of European countries terminal regulation approach: the very heterogeneous importance of railway terminal infrastructure in number of stations and traffic activity, the existence or inexistence of a neutral entity in charge of railway terminal management, the types of charges and revenues (regulated and unregulated) that this entity manages (Teixeira et al., 2013). In Sweden, autonomy is at its maximum (Alexandersson and Rigas, 2013). Terminal ownership and management is carried out solely, by an independent company named Jernhusen, which is fully public owned (state and local governments are involved). The main task of Jernhusen is to manage land, technical and commercial assets as well as offices and housing buildings in the vicinity of terminals and stations. All other European countries include terminal management entities either as an element of the infrastructure manager, or, more rarely, in a department, a branch or a subsidiary with closer contact to former monopolistic train operator. In Germany, Deutsche Bahn Station&Service AG is a legally independent holding company created during the reorganization of Deutsche Bahn. This is equivalent in Spain, where stations are conceived and operated

Table 1 Overview of European countries terminal regulation approach : railway terminal infrastructure and activity, existence of a neutral entity in charge of railway terminal management, types of charges and revenues.

	Number of stations	Number of train stops (in Millions)	Annual number of passengers (in Millions)	Entity responsible for the management of railway station	Number of railway undertakings using passenger stations	Station segmentation	Number of application charges (main service package) and modulations	Publication or negotiation and regularity of tariff renovation	Unregulated revenues (eg retail)
Austria	1438	20	278	Infrastructure Manager	Limited number	yes	66 tariffs	Yearly published	Yes
Belgium	550		225	Incumbent railway undertaking	Limited number	no	1	Yearly published	Yes

France	3029	40	1600	Incumbent railway undertaking (holding)	Limited number (Thello & Thalys)	yes	173 tariffs x 9 modulations	Yearly published	Yes
Germany	6547	152	2700	Incumbent railway undertaking	Multiple railway undertakings (opened market)	yes	196 tariffs x2 modulations	Yearly published	Yes
Greece	376		7,4	Infrastructure Manager	Limited number	yes	included in the charges for the use of infrastructure	Yearly published	
Hungary	1367	13,5	146	Infrastructure Manager	Limited number	yes	4 station segments x 2 modulations	Yearly published	
Italy	2260		855	Infrastructure Manager for most Stations + Grandi Stazioni	Limited number	no	track access included in the station charges for minimum access package		Yes
Luxembourg	68	129	21,5	Infrastructure Manager	Single railway undertaking	no	1 tariff + Extra fees for long trains	Yearly published	
Norway	336			Infrastructure Manager	Limited number	no	2 (one is zero, 1 for the city -airport line)	Yearly published	Yes
Poland	2730	21	269	Infrastructure Manager	Multiple railway undertakings (opened market)	yes	15 tariffs	Yearly published	
Slovenia	273		15,5	Infrastructure manager	Single railway undertaking	yes	4 tariffs		
Spain	1939		470	Infrastructure manager	Limited number	yes	3 tariffs x 4 modulations		Yes
Sweden	136		205	Specific entity Jernhusen	Multiple railway undertakings (opened market)	yes	6 tariffs x modulations		Separated account
United Kingdom	2537	89	1640	Infrastructure Manager in most cases + specific entities related to HS	Multiple railway undertakings (opened market)	yes	differs for each station	Partly published and partly negotiated every 5 years	Yes

Source : Teixeira P., Prodan A., Lopez Pita A., 2013 *Railway stations and auxiliary charges in 27 European countries, final report*, International Railway union UIC and IRG-Rail, 2015, *Overview on charging principles for passenger stations in Europe, technical report*, vol 15, n° 8, 23 p.

by infrastructure entity ADIF; as well as in Austria where ÖBB-Immobilienmanagement GmbH is 100% owned by ÖBB-Infrastruktur AG; and in France, where passenger terminal management and development Gares&Connexions, which was initially created as an autonomous holding within the historic company SNCF, is recently reintegrated to infrastructure manager SNCF Réseau.

The situation is on the opposite in Netherlands, where NS Stations is a specific body integrated in Dutch public owned train company NS; as it is in Switzerland, where stations are managed as part of CFF passenger department; as in Belgium, where SNCB has the control of stations buildings, platforms, car parks and retail. Italy and Great Britain presents specific cases, in the way that a horizontal division is created, that is to say that different kinds of stations obey to different regulation systems. In Italy ([Arrigo and Di Foggia 2013](#)), railway infrastructure manager RFI operates the great majority of stations, save the 14 biggest, under the responsibility of Grandi Stazioni, a body more oriented toward station asset management and opened to corporate groups and private funding. In Great Britain, only the main larger stations are managed and operated by the mainline Infrastructure manager, Network Rail, and the rest of stations are being a part of a franchise and managed by the franchised railway undertaking. High Speed stations are regulated apart. In the case of High Speed 1 line, Saint Pancras station and its five-star hotel were purchased and developed as a property asset in the context of the high-speed regulation system.

Charging Patterns for Railway Terminal Use Across European Countries

In most of European countries, the charging models obey to a common structure and are based on the principle of full cost. The methods used to set the charges are quite similar since the charging system aims at covering all the costs of the passenger station managers. But the situation is also very different from one country to another ([IRG-Rail, 2015](#)). To illustrate this, let us consider that the document Irish rail access charging system is a text of 12 pages where terminal access conditions take no more than three pages, whereas French “Document de référence des gares de voyageurs” has 66 pages. In few cases, such as Ireland, there is no specific charge for passenger stations since such charge is included in the charge for the use of infrastructure. In the other cases, the structure of charging systems is the following. In the majority of cases, a station manager develops a station segmentation using station characteristics and variables (passenger frequentation, traffic intensity, platforms number) and service characteristics. Moreover, according to the European norm, station charges are included into three possible categories: minimum access package fees, additional services, and ancillary services. The first group includes some criteria defining the infrastructure and some other elements describing the services provided in the station by station manager or by other providers. Among them, the use of common spaces and equipment (furniture, lifts, escalators, toilets); the reception, information, and orientation system (audio and display); the reception of persons with reduced mobility; other services such as heating, surveillance, lost & found objects. The second group includes train parking facilities in adjacent depots, energy (preheating and precooling of trains) and water sources and maintenance facilities. Auxiliary or ancillary services refer to other services, such as access to information network, specific conditions for the announcement of trains, maintenance and inspection of vehicles, train dispatching services. Each criteria presence and weigh in the final pricing method is different from one country to another, and external charges (that is to say charges exterior to the three groups) are applied for the access and use of terminal premises (e.g., offices and desks, spaces for ticket sales, railway undertaking personnel) is applied in Austria, Bulgaria, France, Italy, and Luxembourg.

Table 2 shows railway station and terminal charging structure and most used criteria for pricing methods. Station tariff systems differ greatly. Some countries have tariff systems for line charges, but not for stations. Other countries have relatively simple systems (that is to say that stations are categorized by only few variables). However, some countries have built highly complex station pricing systems, whose structure depends on numerous variables. According to a 2015 UIC Study, 16 on the 27 European countries have some type of stations charges or auxiliary charges, 11 have only station charges, nine countries defines their station charges only by categorizing the stations by importance. Concerning the importance of station prices on the global price of access to network, the situation differs greatly between countries, types of network (for example, access to high speed station are much more expensive than access to conventional station) and between different pair of cities (origin–destination). France, Belgium, and Spain have the highest price levels (regularly between 8% and 15%, sometimes 20% of total access price to network) and also the greatest difference between prices for small or medium sized station and prices for bigger stations. Concerning routes, the maximum stations charges observed account for 40% of total infrastructure charges, but remains as an exception.

Hot Topics and Future Trends in Terminal Regulation

The implementation of neutral access conditions and transparent charging systems remains a problem in many countries of Europe. Some of the convergence opportunities expected by Crozet in station charging did not occur ([Crozet 2004](#)). [Tomeš and Jandová \(2018\)](#) have evaluated the international lines between Austria, Czech Republic, and Slovakia. They state that new entrants have caused major increases in train frequencies and cut prices. Yet, given the diverse pathways and levels of liberalization of rail activity in each country, significant problems remain. For example, when Austrian newcomer WESTbahn tried to access infrastructure and other essential facilities, it had difficulties in obtaining attractive timetable slots and its passengers could not easily use ticket selling facilities in terminals. «Further complaints included discriminatory path allocations and the exclusion of WESTbahn services from the timetable published by the incumbent» (p. 76). The construction of fees for using station and terminal facilities remains also very heterogeneous and continues to evolve as a consequence of the European Directives transposition slow rhythm in national laws. But

Table 2 Railway station and terminal charging structure and most used criterias in pricing methods

		Main Variables used in the pricing method
Station segmentation	Station characteristics	- Station category and size - Train traffic - Passenger traffic - Platform number and size
	Service characteristics	- Service type, - Stop type, - Trip length - Stopping type - Peak vs off peak pricing
Minimum access package	Station physical infrastructure descriptors	- Signage - Information area - Seating - Loudspeaker - Platform displays, - Escalator, lift - Security cameras - Garbage bins, - Trolley base - Ticket machine + ticket gate - Weather canopy - Bike parking
	Minimum Proposed Services	- Cleaning service - Security service - Info point - Announcement - PRM service
Additional Services		- Train parking facilities, - Water, wastewater disposal - Preheating /cooling facilities - Maintenance facility
Auxiliary / Ancillary Services		- access to telecommunication networks - provision of supplementary information (eg intermodal information) - technical inspection of rolling stock - Specific ticketing services (eg smart card, intermodal pass ...) - Heavy maintenance

Source : EU Directives 2001 and 2012, IGRail, UIC

even if it is an uncertain and a long-term process, some trends can be observed. First, the “Europeanization” of stations is a strange process in the fact that adapting to the principles of competition leads simultaneously to the standardization of a general regulation pattern and to a specific situation in each country: that is one of the odd consequences of a long term movement of “europeanization of infrastructure” (Schipper 2011). Second, Beria et al. (2012) consider that terminal regulation (and in a broader approach of railway regulation) in biggest European countries (Germany, France, Spain, Italy) shows a balance between liberalization trends and a protectionist attitude from incumbent railways against liberalization, “with the states backing this behavior” (p. 110). The hypothesis is the same in Finger and Messulam, who consider that “the complexity of terminal access charges are not a market tool for pricing the use of rail infrastructures, but rather should be seen as public policy tools” (Finger and Messulam, 2015, p. 12). Third, if station management companies still play a dominant role as railway terminal infrastructure technical operators, but some of them consider to be as well service providers in vertically integrated structures and experts in travel retail and urban real estate. In this objective, some terminal management bodies progressively distinguish subdepartments (some with highly technological approach of flow management, some with a more strategic position of asset managers). These entities use all the possibilities of railway regulation to multiply and diversify the contractual relationships with other businesses, gradually evolving from a framework based on concessions (e.g., restaurant or hotel concessions) to another based on licenses, concessions, contracts, PPPs. Such terminal owners and/or managers consider their mission to be based not only on infrastructure providing, but on infrastructure plus service providing. Each national regulation system can limit or support this orientation. In some countries, unregulated

revenues can either be completely excluded from the regulated charging system (when there is one, as in some European countries), or fully or partially taken into account.

An optimistic vision would state that, in Europe, the terminal manager has the capacity to sell services, to earn the revenues and to reinvest part of benefits in infrastructure projects, or in the train operating budgets, thus decreasing the price of train ticket and, as a final consequence, fostering train competitiveness. A pessimistic vision would consider that terminal managers specialization in service activities make them prefer managing big and rentable stations to small ones, thus threatening the integrity of network. Small stations and terminals may be less rentable but their openness may be considered as a public service obligation, and state or local governments have, in the European regulation system, few tools to support such policy. Station managers that are focused in priority on the production of economic results and are completely dissociated from other railway activities can also be invited to turn station into retail places and threaten overall railway sustainability, performance, and attractiveness in the long term. Another unresolved issue concerns the way station manager will regulate themselves and/or follow overall regulation concerning big data production, openness, treatment, and commodification. These are crucial questions, giving the importance of good and passenger flows in railway terminals and the possible use of such information for a great quantity of service providers. Anyway, such transformations deeply change the governance and the nature of interactions between terminal entities, railway authorities and other stakeholders. The provision of terminal-bound services has shifted from being primarily a railway intraorganizational to an interorganizational task building on the idea of negotiation across a variety of economic sectors, among different levels of government, and between public and private actors, owners and contractors, consultants, and the end-users (consumers and passengers) themselves.

Summary and Conclusions

This chapter has presented an overview of terminal railway regulation principles and implementation. It has described the constitution of terminal infrastructure. It has defined the concept of essential facility since its birth in 19th century US railway race to its regulatory implementation throughout the world, but especially in Japan, Europe and other Asian countries. The results and principal conclusions of the chapter are the following ones.

1. Terminal regulation transformations are caused by from two mains factors: (1) the transformative relationships between State, rail infrastructures, transport companies, and other stakeholders; and (2) the growing diversification of terminal functions, especially service, retail, land development, etc.
2. European institutions has framed specific regulation conditions and access conditions for terminals in the whole Union, but regulatory and pricing schemes remain different in the 27 countries analyzed.
3. Consequently, there is slow and heterogeneous pathways to free and indiscriminate access to terminals in Europe and only a few countries take the opportunity of their progressive autonomy from railway incumbents to develop side businesses in the context of regulated or in nonregulated railway models.

Biography

Nacima Baron holds a PhD in urban planning from Sorbonne University. She is full professor at Paris School of Urbanism at University Paris Est and also teaches transportation planning and urban projects at TU Delft and Rabat University. She holds a chair of railway station development and collaborates to various research projects on station retail, station and railway redevelopment schemes, and smart mobilities.

Introduction

The literature on railroads and railroad planning goes many years back. Several survey papers synthesize the story and contributions of operations research to railroad planning, for example, Assad (1980b), Dejax and Crainic (1987), Crainic (1988), Cordeau et al. (1998), Crainic (2000, 2003, 2009), Newman et al. (2002), Ahuja et al. (2005), Crainic and Kim (2007), Bektaş and Crainic (2008), Yaghini and Akhavan (2012), Piu and Speranza (2014), and Chouman and Crainic (2020). This chapter follows the last contribution. See Crainic and Hewitt (2020) and Crainic et al. (2020) for service network design and applications to consolidation-based transportation.

Railroads move large quantities of products, for example, bulk materials (e.g., grains, minerals, petroleum, and chemical products), general packaged freight, containers, trailers, automobiles, and machinery. Railroads are particularly efficient for long-haul movements in terms of per ton-km monetary, energy-consumption, and pollutant-emission costs. The transcontinental North-American land bridge between the West and East coasts, and the Eurasian land bridge between China and Western Europe bear witness to this efficiency. Freight rail transport is thus an essential link of intermodal transportation and supply chains, supporting national and international trade.

To achieve this efficiency, railroads operate mostly as consolidation-based carriers, similar to less-than-truckload trucking and liner shipping, for example. Consolidation offers the means to take advantage of economies of scale and reduced handling in terminals, by grouping freight from different shippers, with possibly different origins and destinations, and loading them into the same vehicles for efficient long-haul transportation. Railroad consolidation policy generally involves two levels, however, as cars are grouped into blocks, which are then grouped into trains. Loaded and empty cars, with different origins and destinations but being present simultaneously in the same terminal, are thus sorted and grouped into a block, which is then moved as a single unit by a series of trains until its destination, where it is broken down, the cars being either delivered to their final consignees or sorted for inclusion into new blocks.

The performance and profitability of the carrier then depends, for a large part, on efficient and coordinated terminal and long-haul transport operations, supported by an efficient management of resources, providing an offer of service meeting the cost/profit objectives of the railroad and the cost and quality criteria of its customers. Tactical planning aims to address this challenge through a network-wide transportation plan stating the train services to operate, the routing of the customer demand by those services, and the associated yard and line activities. The problem is complex and difficult to address, involving many decisions linked in a web of economic, resource utilization, and time-performance objectives, limitations, and trade-offs.

Service network design (SND) is the methodology of choice to build tactical plans for consolidation-based railroads, making the most efficient use of resources to achieve economic and customer-service performance objectives. This chapter provides a high-level overview of freight railroad planning and the service network design models and methods proposed to address it. Space is limited. Consequently, fundamental modeling concepts are discussed only, with pointers for further reading and more in-depth study. Chouman and Crainic (2020) provide detailed models for various cases, together with solution-method discussions and a rich literature review.

The paper is structured as follows: section “Rail Freight Transportation Structure and Planning” presents brief descriptions of rail freight transport and associated tactical planning issues; section “Service Network Design for Railroad Planning” is dedicated to the main SND problem settings and models: basic concepts and problem structure (section “Basic SND and Service-Selection Planning”), followed by integrated-planning models for the static (section “Static SND for Integrated Planning”) and time-dependent (section “Time-dependent SND for integrated planning”) cases; section “Using Service Network Design Models” discusses the utilization of SND models for railroad planning and the chapter concludes in section “Conclusion.”

Rail Freight Transportation Structure and Planning

We present brief descriptions of rail freight transportation and tactical planning.

Rail Freight Transportation System

Railroads operate on an infrastructure made up of a large number of terminals and rail tracks linking them. Most terminals are stations where demand originates and terminates, while a few are the yards specially equipped to handle large quantities of cars, sorting and grouping them for long-haul transportation, as well as to make up and disassemble blocks and trains. The backbone component of this network is made up of main lines connecting the yards of the system. The network is completed by secondary lines used to move loaded and empty cars between stations and their designated yards. Tactical planning targets operations on this main physical network.

Customer demand concerns a number of cars (containers to be loaded on special cars in the case of intermodal transportation), of a type appropriate to the commodity to be moved, to be shipped from an origin station, yard at the tactical level of planning, to a destination one. Empty cars, which need to be repositioned for the next cycle of operations, are also part of the demand. Each origin–destination (OD) demand is characterized by a volume, in terms of number of cars or containers, an availability time at the origin, and a due time at destination. For tactical planning, demand is an estimation of the “regular” traffic the railroad expects to satisfy over the planning horizon.

Freight is moved by train services, each composed of one or more locomotives providing power and a series of cars. A *service* is made up in an origin yard with a final destination yard, where it delivers the cars currently hauled and liberates the locomotives. En route, it may stop at a number of intermediary yards to deliver or pick up cars, eventually grouped into blocks as described below. The service is also characterized by time-related information, which may take the form of a frequency of service, that is, the number of times the “same” train is run during the schedule length (the length of time the railroad uses to define its recurring operations, for example, one week), or a schedule indicating the departure time from the origin yard, arrival and departure times at each intermediary yard, and the arrival time at destination.

Railroads aim to maximize revenue, which often translates into achieving the best balance between the cost of operating resources and services, on the one hand, and the quality of the service measured according to customer expectations in terms of timely and reliable delivery, on the other hand. Railroads therefore operate direct trains for important customers only or when the demand volume between two stations is significant (e.g., the equivalent of at least a full train). Most of the time, railroads rather aim for economies of scale through consolidation of cars from different demands into blocks and of blocks into trains (blocking is less performed when trains are short, e.g., in Europe). Schematically, cars at their origin yard are sorted, classified is the term generally used, to be then grouped into particular blocks with other cars, with potentially different origins and destinations. The block is then handled as a single unit from its origin yard, where it is formed, to its destination yard, where it is taken apart, its cars at their final destination being delivered to the respective consignees, the others being reclassified and blocked with other cars present at the yard for the next part of their trips. Services are thus made up of blocks and, when appropriate, it is blocks that are picked up and delivered at intermediate stops. Blocks may thus be transferred from one service to another.

Notice that intermodal traffic (containers and trailers) is often handled separately from the general one, both in yards and on the tracks, being moved on dedicated services. The most important difference, however, concerns the loading and unloading of intermodal traffic, which is performed in particular zones of the railroad’s yards. Numerous types of containers and cars exist, yielding a large number of loading alternatives subject to many rules and limitations, particularly when double-stack loading is permitted as in, for example, North America (Mantovani et al., 2017). Accounting for this complex issue at tactical planning level is particularly challenging.

The double (triple for intermodal) consolidation organization of freight railroads provides the sought-after economies of scale in operation costs and resource utilization, reduces car handling activities at yards, and fosters a timely service for pairs of cities or regions with low traffic volumes. It also implies more complex operations in terminals, with potentially higher possibilities for delays and incidents, which translate into more complex decision-making problem settings. Service network design models and methods are proposed to address these challenges.

Freight Railroad Tactical Planning

The planning activities of rail operations may be broadly classified into three levels: (1) strategic, involving long-term decisions on, for example, system design and acquisition of major resources (e.g., buy or rent locomotives or cars); (2) tactical, medium-term

planning process dedicated to building for the next “season,” an efficient service and resource-utilization network and schedule, specifying the train services to operate, the blocks that will make up each train, the blocks to be built in each terminal and the sequence of trains moving them, and the routing of the cars, empty and loaded, using these services, blocks, and terminal operations; (3) operational, concerning the short-term planning, monitoring, and adjustment of operations.

We focus on tactical planning in this chapter, as it yields the plans and policies of which depends the efficiency of the railroad. The service network design models discussed may also be used at the other levels of planning (Chouman and Crainic, 2020).

The tactical plan is built for a rather short schedule length (e.g., a week), to be repeatedly applied over the season (e.g., six months). Planning occurs some time before the season starts. Thus, even though some part of demand, for example, long-term contracts with customers, may be known at planning time, most is forecast using history, customer-relation representatives’ knowledge, and customer input, among other data sources. The goal is to satisfy the forecast regular demand in the most efficient way possible with respect to costs (profits) and resource-utilization, while satisfying the service-quality levels set by the carrier to answer customer requirements.

A number of main decisions/issues make up the tactical planning process and are addressed through SND models and methods, namely:

- *Service selection* selects among a set of possible services, which ones to operate the next season to move demand efficiently, profitably, and on time. The set of alternatives may represent a complete yard-to-yard network with intermediate stops for all service types, or the last-season network enriched with new potential services to address changes in demand, economic environment, railroad policies, etc. The resulting service network specifies the movements through space, and time for scheduled railroads, of trains and cars.
- *Blocking and classification* focus on how cars are grouped in yards yielding the blocks to be moved by trains. A *block* is characterized by its origin and destination yards, sequence of yards on the infrastructure network where it is transferred from one service to another, the sequence of train services performing the transportation. Blocking selects the blocks to build at each yard. Classification defines how cars are sorted and assigned to blocks at yards. For intermodal services, the problem also includes the assignment and consolidation of containers to multiplatform cars.
- *Train makeup* yields the list of blocks, and cars, each train service hauls out of its origin yard, drops and picks up at intermediary stops, and delivers at its destination yard.
- *Freight routing* determines the *itinerary*, or itineraries when splitting of demand is allowed, to transport each demand from its origin to its destination through the selected service network.

Resources, for example, locomotives and cars, are required to operate services. Resource management assigns the appropriate resources to services, and determines the economically, maintenance, and operationally efficient resource movements over the schedule length. Resource management is generally considered an operational-level managerial activity (Cordeau et al., 1998; Dejax and Crainic, 1987; Piu and Speranza, 2014) and its impact on tactical-level decisions was often limited to the somewhat simple case of accounting for the need to reposition empty cars for the next cycle of operations. The situation is evolving, however, and resource-management concerns are increasingly part of SND models for tactical planning (Andersen et al., 2009; Chouman and Crainic, 2020; Kienzie et al., 2020; Pedersen et al., 2009).

These problems may be, and have often been, addressed individually reflecting a planning process decomposed into a sequence of decisions. The strong and complex interconnections among these decisions increasingly lead, however, to integrated approaches addressing several problems jointly. Such approaches do not make problems easier, however, as planning must be performed network-wide aiming for the best trade off among the not necessarily convergent operational, service-quality, and economic characteristics of the individual problems and decisions. Thus, for example, one could try to increase the level of service by increasing the frequency of services, but this could result in higher levels of congestion in yards and on the tracks, resulting in increased costs and delays and, thus, possibly, a lower quality of service (increased costs as well, of course).

Service network design provides the methodology to model the rail freight transportation dynamics at a network-wide level, integrating the different operations, decisions/issues, objectives, and trade-offs, yielding an optimized operation plan for the season.

Service Network Design for Railroad Planning

Service network design (Crainic and Hewitt, 2020) models are built on networks representing the railroad’s structure, activities, and decision-to-be-made, and take the form of multicommodity, capacitated fixed-charge network design formulations (Crainic et al., 2020).

The problem and SND model are called *static* when one assumes that neither demand nor the other problem characteristics vary during the schedule length considered. The time dimension of the service network is then implicitly considered through the definition of services and the inter-service operations at terminals. The main decision in such cases is whether a service is selected to be included in the plan or not (its frequency, if selected, over the schedule length may be part of the decision). *Time-dependent* problem settings and formulations address the cases when the moments demand becomes available and is due at destinations are explicitly considered, which implies an explicit representation of demand and activities in time. Time-dependent formulations, called *scheduled service network design* (SSND), target the selection of services together with their respective schedules indicating arrival and departure times at yards.

Reflecting the traditional goals of railroads and expectations of customers to “get at there at the lowest possible cost,” the primary objective of these models is the minimization of the total operating cost. This cost is computed mainly as the sum of two terms, which may take different forms according to the problem and model considered (more on this shortly). The first represents the total cost of setting up the service network based on the fixed costs of the services. The second computes the cost of moving the freight given the service network, based on the commodity volumes moved by each service leg and the corresponding unit transportation costs.

Service-performance measures are increasingly included in tactical planning and SND models, reflecting rising customer expectations for high-quality service and environmental concerns. They are generally modeled through delays incurred by freight and resources or the amplitude of violation of predefined performance targets (e.g., delivery within a given time length). Constraints may be imposed on these service-performance measures, or one may add them as costs and penalties to the objective function of the SND formulation. The resulting generalized cost function then captures the trade-offs between operating costs and service quality.

All SND models addressing rail tactical-planning issues share the same structure. The basic problem setting and SND formulation are presented first, followed by more general static and time-dependent cases. See [Chouman and Crainic \(2020\)](#) for detailed presentations and literature review.

Basic SND and Service-Selection Planning

SND modeling starts with a network representation of the railroad physical infrastructure, where nodes represent yards, while arcs stand for the physical track paths between adjacent yards. Capacity measures are attached to nodes defining, for a given time period, the yard capacity to classify (number of cars that can be sorted and assigned to blocks), to block (number of blocks which can be built), to transfer blocks (number of blocks), and to make up train services (relative to the number of available tracks or resources). Capacity measures may be also defined for arcs reflecting the physical or operational limits of each track on, for example, the number of trains that may operate “simultaneously” (following, meeting, or overtaking), or the total weight or length of train on the track (the latter translates lower and upper limits on the block length and weight).

The demand side of the system is represented by a set of OD commodities, each commodity standing for the request to move a given volume of freight (number of loaded cars or containers, generally) from its origin yard to its destination yard. Demand is moved along itineraries, each specifying the sequence of blocks, services, and yard classification and transfer activities, between the demand origin and destination. These itineraries are defined on the network supplied by the train services the railroad runs on the physical network.

Services to include in the operation plan are selected from a set of potential services, each one being characterized by a path in the physical network between its origin and destination yards, as well as by a number of characteristics in terms of, for example, hauling power, speed, and priority. Single-leg services operate nonstop between these yards, while multileg services stop at one or several yards on the route to drop and pick up blocks and cars. Several cost and capacity measures may be associated to services depending on the particular problem addressed. In almost all cases, however, one finds the fixed cost to select the service (including, depending on the application, the costs for making up, dismantling, inspection, power, crews, etc.), the leg and commodity-specific unit transportation costs (including weight and handling-related costs), and the leg-specific capacity standing for the volume of demand the service may haul on each leg (determined by the physical and operational characteristics of the tracks).

Each SND model is then defined on a network based on the physical one and the set of potential services. We present the general SND-modeling framework in the context of the service selection and train makeup problem setting (e.g., [Assad, 1980a](#)). This problem arises when no blocking is performed (e.g., most European railroads), or blocking is performed once the main service network is decided. Given the set of possible services, the problem aims to (1) select the services to run and their frequencies over the planning period, and (2) assign cars to trains and determine the associated freight routing to accommodate all demand at minimum cost. As in all problem settings considered in this chapter, freight routing may involve single-service demand itineraries, and itineraries with service-to-service transfers at intermediary yards. The latter require time and resources, generating costs and possible delays. These concerns must be accounted for in the cost representation.

The nodes of the SND network are those of the physical one. The service legs of the potential services make up the arcs. Two main sets of decision variables are defined on this network. Binary *service design* variables indicate for each service if it is selected (variable will take value 1; when frequencies are included, this value becomes a non-negative integer) or not (value equals 0). Non-negative continuous *flow* variables are defined for each commodity on each service leg and stand for the demand volumes assigned and transported on each leg. Auxiliary binary decision variables model decisions to transfer commodity-specific flows at yards. Unit handling and transfer costs are given for each commodity and yard. The SND model yields an optimal operation plan, given by the values of the design and flow variables in the optimal solution, by minimizing the total generalized cost of the plan, subject to flow conservation and capacity/linking constraints.

The generalized-cost objective function is the sum of service selection and operation (total fixed cost of selected services), transporting the demand on the selected services (the sum over all commodities and service legs of the volume moved multiplied by the corresponding unit cost), plus the cost of car transfer at yards (a fixed cost associated to the transfer decisions or, a nonlinear penalty function of the decision to transfer and the quantity transferred).

The first set of constraints is typical of all network-flow optimization problems, enforcing the demand-satisfaction requirements, and the conservation of commodity flows at the nodes of the network. The linking constraints ensure that the total flow on any service leg cannot exceed the capacity of the service on that leg, provided the corresponding service is selected. Constraints identifying

the commodities and yards involved in transfers, as well as enforcing the integrality and non-negativity of the decision variables complete the model.

Static SND for Integrated Planning

The previous model may be easily adapted to address other tactical-planning issues, blocking in particular (e.g., Ahuja et al. 2007; Barnhart et al., 2000). We rather discuss an integrated SND static model (e.g., Crainic et al., 1984) aiming simultaneously to select the service and the block networks and, thus, define the classification strategy, as well as to determine the demand itineraries, establishing how freight is to be routed through the service and block network.

The integrated SND model is built on the same network of potential services defined in the previous subsection, and the yard and service definitions and characteristics are the same as well. The car classification and blocking set of issues and decisions need to be added.

Recall that cars, with possibly different origins and destinations, are classified and grouped into blocks, which are moved by trains and are handled as a single unit from their origins to their destinations. Recall also that cars at their origin yard may follow itineraries where they are classified and assigned to a block which brings them to their destination yard, from where they are to be delivered to their consignees. Alternative itineraries may also be used where the initial block brings cars to an intermediate yard, where they are reclassified into new blocks, and continue their trip toward the final destination or another intermediate yard and reclassification. More than one reclassification may make up the itinerary. The yard characteristics are enriched to account for these activities by defining for each yard, the unit car classification cost and the maximum numbers of cars which may be classified, blocks one may build or transfer, and trains one may make up.

Similarly to the service definition, one defines the set of potential blocks linking the yards of the network, each block being defined by (1) the sequence of yards where it is formed (origin), dismantled (destination), and transferred from one service to a different one; and (2) the sequence of service legs transporting the block from its origin to its destination, through the transfer yards, when relevant. A fixed cost, representing the building, transferring, and dismantling costs, and a capacity (the same units used for services) further characterize blocks. Commodity-specific unit transportation costs are associated to each block (based on corresponding leg-specific costs).

Sets of design and flow decision variables are again defined. To the integer service design variables, one adds the binary block design variables, which indicate for each block if it is selected or not. Non-negative continuous flow variables are now defined for each commodity on each block (instead as service legs as previously). The objective is still to minimize the generalized cost of the operation plan. The total block selection and operation cost (accumulation of the fixed costs of selected blocks) is added to the total service selection cost. The total cost of transporting the demand on the selected blocks (and services) and the total car classification cost at yards complete the objective function. The flow conservation constraints are part of the model, as well as linking constraints that state that a block cannot be used unless all the services moving it are selected. Linking/capacity constraints play a similar role for car assignment to blocks and services (cannot assign to nonselected blocks and trains). Constraints enforcing the yard capacity measures, and enforcing the integrality and non-negativity of the decision variables complete the model.

Chouman and Crainic (2020) detail this model and its path-based version, as well as more advanced formulations addressing congestion-induced delays, nonadditive itinerary attributes (e.g., tariffs), and penalties for violation of dues dates or other service-quality measures.

Time-Dependent SND for Integrated Planning

Scheduled service network design, SSND, targets time-dependent problem settings, where time and service schedules are explicitly considered. SSND formulations are built on *time-space* networks, using a discrete (more rarely, continuous) representation of the schedule length. A discrete representation of the schedule length is obtained by defining a sequence of time instances, from the start (time 0) to the end of the schedule, a time period in this representation corresponding to the length of time between two consecutive time instances.

The set of nodes of the time-space network includes copies of the yards in the physical network at all the time periods defined (this definition may be made specific to each yard). Each demand is defined on the time-space network and, thus, further characterized by an availability time at origin and a due time at destination. Each potential service in the SSND context is similarly defined on the time-space network. The sets of yards and service legs identifying it now being defined by nodes with a physical identify and time-related attributes, namely, arrival and departure times at the yards where the service originates, stops, and terminates. These define the service *schedule*.

The SSND network is completed by a set of arcs, which includes moving and holding arcs. The former correspond to the legs of the potential services, an arc being defined for each service leg. The latter are arcs connecting two time-consecutive representations of each yard, and represent the possibility for equipment and freight to wait at a terminal for a time period.

Recalling that the scheduled service plan is to be applied repeatedly over the season, the time-space network is cyclic to reflect the fact that activities and decisions do not stop with the end of the schedule length, but rather involve the next application of the plan. Thus, for example, when building a week-long schedule, a service may start on Friday and arrive at destination the following Tuesday. These situations are modeled through “wrap-around” arcs (when the destination time of an arc is later than the end of the schedule, the destination time is set to the corresponding time in the current schedule through a modulo computation).

The general SSND integrated-planning modeling framework addresses the same main tactical-planning issues identified before, service selection and scheduling, blocking and classification, train makeup, and freight routing. The goal is again to minimize the total generalized cost of the system, while satisfying demand with the available resources. The notation, definitions, and structure of the mixed-integer network design formulation introduced for the SND case above applies to the time-dependent SSND case, but on the time-space network. The resulting formulations may be very large and require advanced solution methods, but provide the advanced decision-support instruments for the problem.

Chouman and Crainic (2020) detail this methodology in the general case (see also Zhu et al., 2014) and discuss extensions to intermodal settings with continuous time representation (Morganti et al., 2020) and SSND models integrating resource management concerns (Andersen et al., 2009; Kienzle et al., 2020; Pedersen et al., 2009; see also Crainic and Hewitt, 2020).

Using Service Network Design Models

The service network design methodology developed for tactical planning may be used rather broadly to address other railroad planning problems.

SND and SSND models may be expanded to include strategic-level decisions, for example, investments to enhance infrastructure, acquisition or renting resources, and outsourcing service in particular regions. An extra design layer is added to the formulation to represent the strategic alternatives to choose among, the tactical-planning layers providing the evaluation of those decisions within the global optimized plan (Crainic et al., 2018; Hewitt et al., 2019).

The tactical formulations may also be directly used as a simulation tool to perform cost-benefit analyzes and evaluate the impact of strategic scenarios on operations, resources, and system performance. Typical scenarios may concern variations in, for example, economy (e.g., fuel prices or changing production and consumption levels of certain goods), laws (e.g., emission charges or trade restrictions), or regulations (e.g., speed and weight limits when carrying hazardous goods).

The service network design formulations may also be adapted to review, weekly for example, the tactical plan built for the season. One would then re-optimize and adjust the plan and operations to current conditions. What may be adjusted depends strongly on the railroad application context. Canceling or adding services on a short notice is not easily performed by railroads and SND models may assist in selecting the best alternative and determining the network-wide impacts. Updating the actual demands or resources, or both, assigned to blocks and trains is taking place quite often within railroad management and, again, SND models are appropriate.

Conclusions

The chapter presented a high-level overview of freight railroad planning and the service network design models and methods proposed to address its challenges, as well as pointers to further reading and more in-depth study.

It is noteworthy that this is a field still evolving, both in how freight railroad transport, and the world around, evolves and in the modeling and algorithmic challenges these application raise. Chouman and Crainic (2020), and the references cited therein, identify several important research perspectives. We do not have the space here for an extensive list. We emphasize only the need for significant research efforts in (1) the integration of the main components of railroad planning at the tactical level, from scheduled service selection to resource management; (2) the development of efficient solution methods for large problem instances, including the dynamic generation of the sets of potential services and blocks, decomposition methods, and parallel optimization; (3) the study and explicit integration of uncertainty, in demand and travel and yard-activity times, into SND planning models and the development of appropriate solution methods; (4) the definition of revenue management mechanisms for rail transport and the study of the interactions between these operational-level mechanisms and tactical planning processes and service network design models and methods.

Acknowledgments

The author wishes to address the warmest thanks to the collaborators and students who worked with him over the years to develop models and methods for network design and railroad planning. The research benefited from the environment offered by the CIRRELT, its staff and professionals. The author thanks these individuals, as well as the Fonds de recherche du Québec, the Université du Québec à Montréal (UQAM) and the Université de Montréal (UdeM), for the financial contributions, the infrastructures and the resources they offer through the CIRRELT. The author also gratefully acknowledges the research-funding support of the Government of Canada, through its NSERC programs, of the Government of Québec, through its FRQ programs, and of public and private partners. The author holds the Chair on Intelligent Logistics and Transportation Systems Planning of UQAM. The financial contributions of ClearDestination and NSERC to the Chair are gratefully acknowledged. He is Adjunct Professor, Computer Science and Operations Research Department, UdeM, and Co-Director, Intelligent Transportation Systems Laboratory, CIRRELT.

Introduction

Subway (also called metro, underground, and tube) is an electric railway on devoted rights-of-way, fully segregated from other means of motorized and unmotorized transport. Designed for dense cities, subway systems have a high capacity, able to handle more than 30,000 passengers per hour and per direction.

This chapter relies on several occasions on data from the CoMET and Nova subway benchmarking groups facilitated by the Transport Strategy Centre at Imperial College London. These groups, established in the early 1990s, enable the largest metro operators in the world to share performance data and best practices in a systematic and scientifically rigorous way. Their membership includes Berlin, London, Madrid, Moscow, and Paris in Europe; Beijing, Guangzhou, Hong Kong, Seoul, Shanghai, Singapore, Taipei, and Tokyo in Asia; and New York, Mexico City, Santiago de Chile, and Sao Paulo in the Americas¹.

The chapter has five main sections. Section [A Brief History](#) describes the history of subway systems with an emphasis on major innovations. In Section [Supply](#), we characterize the subway supply through its physical and financial aspects. Section [Demand](#) provides quantitative and spatial information on demand. In Section [Pricing](#), we discuss usual pricing and subsidies schemes. Section [Externalities](#) zooms in on a number of subway-related externalities. Conclusions are provided in the final section.

A Brief History

Early Days and Expansion

The first subway system opened in London in 1863. This 6-kilometer-long line was a great success, with 38,000 passengers on the opening day and 9.5 million passengers in the first year of service. Other cities followed London and built their own subway systems:

¹The full list of benchmarking group members is available online: cometandnova.org.

Fig. 1 Number of subway systems in operation by continent. Source: own elaboration.

Budapest and Glasgow in 1896, Boston in 1897, Paris in 1900, New York in 1904, Buenos Aires in 1913, Tokyo in 1913, and Moscow in 1935. Today, there are almost 200 subway systems in operation around the world (see Fig. 1). The significant increase in the number of systems since the 1970s is mainly driven by Asia, particularly by the opening of several networks in China.

Deeper and Deeper

Over time, subway lines have been built deeper below ground, from subsurface to deep level. The first subway lines were built using the cut-and-cover method: this means that a trench is excavated from the surface, which is then roofed over with an overhead support system. In Paris, the rails are sometimes only 4.5 m below the level of the roadway. For construction convenience, most of the first subway lines follow the layout of the streets above.

The deep-level lines are built with a tunneling shield. These lines are often at a depth of more than 10 meters below ground. Some stations may be more than 100 meters below the ground. The Arsenalna station of the Kiev subway in Ukraine is the deepest in the world: it is 105.5 meters deep. It is followed by Admiralteyskaya station in St. Petersburg (102 m) and Puhung station in Pyongyang (100 m). Grand Paris Express lines are planned between 15 and 55 meters below ground.

Electrification

The first trains were pulled by steam locomotives, which required efficient ventilation from the surface. Ventilation ducts at various points along the route allowed steam locomotives to expel smoke and bring fresh air into the tunnels. However, the use of steam locomotives led to smoke-filled stations and carriages that were unpopular with passengers. As a result, the electrification of the London Underground began in 1890. From then on, all new lines had become electrically powered. Electric power is usually supplied via third (and fourth) rails, in order to save the space that overhead wires and pantographs would require in the underground environment.

Automation

Automation of operations is the latest major technological improvement of subway systems. A subway line is said to be automated when the responsibility of train operations is transferred from the driver to a train control system. The UITP defines five degrees of automation, from 0, which corresponds to on-sight operation, to 4, in which trains run without an operator on board.

Automation may increase the capacity of subway systems, due to a reduction in the safety headway (i.e., the minimum headway between two consecutive trains). The coordination of the acceleration and braking phases also saves energy. Finally, the supply is more flexible because the frequency can be increased without the need for additional driver. The staff savings need to be qualified because the savings made on drivers are partly offset by the creation of new positions to manage the line.

Supply

Network

The length of subway systems varies considerably between cities (the total commercial line length goes from a few kilometers to almost 700 km, see Fig. 2). Some systems serve the suburbs, others only the city center. The network is then complemented by other

Fig. 2 Network length in kilometers of commercial lines of 34 networks in the CoMET and Nova subway benchmarking groups.

means of public transport such as feeder bus services or suburban trains. The topology of the networks is also varied, with networks taking different shapes depending on geographical and historical constraints, travel patterns and construction costs. Roth et al. (2012) studied the 15 largest networks in the world and identified a convergence of network forms towards a form composed of a dense core, fed by branches radiating from the core.

Each subway system consists of one or more lines, distinguished by colors, names, or numbering and served by at least one specific route. Trains stop at all or some of the stations on the line. Lines running through the city center can be separated into two or more branches in the suburbs, allowing for higher frequency service where demand is highest.

The hourly capacity of a line is obtained by multiplying the car capacity (passengers/car), the number of cars per train and the service frequency (vehicles/h). A typical metro line can accommodate 150 passengers per car, 8 cars per train, and 30 trains per hour, giving 36,000 people per hour and direction. Actual maximum car occupancy depends on seating and standing configurations and on the level of passenger crowding that is socially accepted in each city. Fig. 3 provides an overview of the annual supply density for some subway systems in the CoMET and Nova subway benchmarking groups, where supply density is defined as standard vehicle capacity kilometers normalized by the commercial network length. The highest capacity is sufficient for almost 400 million passengers per network kilometer per year, but most networks offer between 50 and 200 million passengers.

Fig. 3 Yearly supply density in million passengers per kilometer of 34 networks in the CoMET and Nova subway benchmarking groups.

Rolling Stock

Subway vehicles are high-performing assets designed for highly standardized, uniform railway operations. The vehicles are almost exclusively electric multiple units with a driving cab at both ends of the train (with the exception of some of the fully automated vehicles). Given that platform length and, in general, station capacity is a critical determinant of the cost of subway construction, vehicles are designed to maximize the proportion of the train length that can be utilized by passengers. Other dimensions of subway vehicles are mainly defined by the diameter of underground tunnels, which is again subject to a trade-off between construction costs and capacity.

Several unique features of subway vehicles are meant to increase capacity and travel speed, as experienced by passengers. High capacity can be achieved by (1) short headways, (2) reduced dwell times by ensuring fast boarding and alighting, (3) effective acceleration and deceleration, and (4) targeting maximum interior capacity utilization within vehicles. The upper bound of service frequency is the minimum distance between consecutive trains, where advanced communication systems are deployed to reduce this gap without compromising safety standards. The ultimate lower bound of the headway is the dwell time itself: the dwell time at the busiest station determines service frequency on the entire line, and therefore speedy boarding and alighting at this bottleneck is critical to overall line performance. To ensure fast acceleration and deceleration, electric power units are distributed along the vehicle, often to each wheel set. Rubber-tire technology, which is unique to the urban rail industry, further enhances traction. Finally, subway vehicles feature lowered seated to standing ratios and large doors to increase total capacity and speed up interior passenger flows for boarding and alighting.

Operator Costs

Among 31 members of the CoMET and Nova subway benchmarking groups, the average breakdown of major expenditure components in 2018 is as follows:

- Operational and service costs: 28.8% (train service costs 13.3%, station service costs 9.7%, service management, and support 5.7%);
- Maintenance costs: 24.1% (rolling stock maintenance 9.1%, infrastructure maintenance 8.5%, and station facilities maintenance 6.5%);
- Administrative costs: 12.7%;
- Renewals and investments: 34.4% (nonexpansion investments 19.9%, expansions completed in the year of observation 3.1%, and ongoing investments 11.5%).

From this breakdown we highlight that the sum of maintenance and nonexpansion investment costs constitute around 44% of all monetary expenditures of subway operators, while 29% is allocated to direct operational costs. This ratio illustrates the presence of substantial fixed costs in the industry, and a relatively small share of operational costs directly related to the firm's final output, that is, the number of passengers carried. Another important inference from this data is that in a representative sample of the global subway industry, almost 15% of all financial expenses are invested into service expansion, which showcases the prevalent growth rate in urban rail transport.

More insights can be gained on the production process and the costs of subway service via statistical modeling techniques. The empirical literature of cost function modeling concentrates on the identification of returns to scale (RTS) and returns to density (RTD) on the level of individual operators and the industry as a whole. RTS measures the impact of firm (network) size on the average operational cost, while RTD relates infrastructure utilization (i.e., service frequency on a network of fixed size) to the average cost. A major challenge in the unbiased estimation of these indices is the potential endogeneity of subway output, which is likely to be affected by the unobserved, subway-specific level of productivity. [Anupriya et al. \(2020\)](#) find strong scale economies with respect to both network size and service density: their RTS estimate is 1.223 while RTD is 1.562, which are higher than the majority of previous estimates that do not control for output and factor price endogeneity. Scale and density economies imply that (1) network expansions lead to external benefits in the form of network-wide reduction in operational costs, and (2) subsidies are justified from an operational cost point of view as well.

Demand

Total Ridership

Subway is a mode of mass transportation that allows to accommodate high passenger density along a transport corridor. A total of 178 metro networks identified by UITP (International Association of Public Transport) provided more than 53 billion journeys in 2017 ([UITP, 2018](#)), compared with only 44 billion in 2013, which represents an increase of over 21%.

This growth in global patronage dissimulates quite different trends across the continents. [Fig. 4](#) shows the annual usage of CoMET and NOVA networks by continent. Asia's leading role in number of networks (see [Fig. 4](#)) is paralleled by the increase in ridership as well, with a 83% increase between 2008 and 2018. Growth is more moderate in Europe (+100 million between 2008 and 2018), whereas ridership increases on average by 13.5% between 2008 and 2018 in Americas subways networks.

Fig. 4 Average network yearly ridership by continent in million trips, based on 34 networks in the CoMET and Nova subway benchmarking groups.

Spatial and Temporal Demand Patterns

The actual route density and direction of lines determine the temporal and spatial characteristics of subway demand. Radial lines are usually characterized by a high demand toward the Central Business District (CBD) in the morning peak and a relatively low demand in the opposite direction. This type of demand unbalances sometimes leads to the application of strategies to increase supply in the peak direction, for example through station skipping and short-turning. Circular lines may have more balanced demand patterns both temporally and spatially, depending on the land use around the stations. [Hörcher and Graham \(2018\)](#) show that the magnitude of demand imbalances has crucial consequences on the financial and economic performance of public transport operations.

Pricing

Subsidies and Value Capture

The amount of subsidy required by a subway system to finance its operations is a subject of intensive policy debates worldwide. Given the presence of strong scale and density economies, competition is rare in the urban rail industry and subways may have substantial monopoly power in the travel market. It is a consensual standpoint in public policy, however, that transport providers should not pursue a profit maximizing objective, and therefore subways are normally under public ownership or subject to strict price regulation.

Economic theory does not offer direct rules to determine the welfare maximizing subsidy. The optimal financial deficit (or surplus) is a derived quantity: an outcome of the optimization of fares and capacity supply, as the latter determines the magnitude of operational costs. In principle, capacity shortages, crowding externalities and costly public funds reduce the optimal subsidy, while the degree of scale and density economies, substitution with car use, the severity of car externalities, and potential agglomeration benefits are typical drivers of increased subsidies ([Hörcher et al., 2020](#)). These parameters may vary on a wide range in large metropolitan areas of the world. However, we observe a tendency of discontent among metro operators who claim that current subsidies are inadequate to maintain a good level of service, cope with increasing demand and customer expectations, and keep expensive assets in good state of repair. One potential explanation is an inconsistency in how long-run operational, maintenance and renewal costs are taken into account by funding bodies, including local and higher level governments.

Theory suggests that pricing policies should be driven by the short-run marginal social cost of subway usage. In practice, prices are set with several different social and economic objectives, subject to an externally defined subsidy, while investments and long-run decisions are evaluated on the basis of separate cost-benefit analyses. If governments do not evaluate the funding need of costly renewals and service upgrades on a regular basis, the financial health of subway operations may become uncertain. Under such circumstances, it has become a popular belief among subway operators that they should achieve financial independence from governments in terms of renewals and investments by covering these costs from commercial revenues. While this belief is a natural response to the uncertainty of government funding, the resulting cost recovery ratios may diverge from their welfare maximizing levels, in the form of fare hikes or sub-optimal capacity provision. Another major trend in the industry is that transport operators intend to increase their commercial revenues from non-transport activities such as real estate development. Once again, this turns out to be an efficient tool to reduce reliance on government funding and ensure financial stability, but if the additional revenues are generated using the operator's monopoly power in the related nontransport markets, then the resulting distortions may offset the perceived benefits from a social welfare point of view.

Fig. 5 Cost recovery ratios by continent, based on 34 networks in the CoMET and Nova subway benchmarking groups.

Fig. 5 plots the evolution of cost recovery ratios among 24 members of the CoMET and Nova metro benchmarking groups between 2008 and 2018. The cost recovery (or self-financing) ratio is the fraction of operational costs covered by fare revenues. Renewals and investment expenditures are excluded from operating costs, while the revenue side includes ticket sales only. We observe that subways in Asia and the Americas are close to full cost recovery. European subways cover a substantially lower share of their operating cost from fare revenues. The plot shows a marginal increase in the ratio from the range of 60% around 2010, which has gradually increased to a stable level of 70%. The density of the urban environment in which subways operate in Asia and Latin America, and the resulting large occupancy levels and capacity shortages, might be a key reason behind the systematic difference in this metric. However, it is worth noting that the standard deviation of self-financial ratios is 0.3 among European metros, and substantially higher, 0.4, for cities in both Asia and the Americas.

Distance-Based Versus Flat Pricing

The way in which the intensity of use, for example, trip length, should be considered in the determination of fares has been a matter of discussion and research in the academic literature (see, e.g., [Kerin, 1992](#), [Jara-Díaz and Gschwender, 2005](#)) and there is no definitive answer on whether or not fares should increase with travel distance. [Turvey and Mohring \(1975\)](#) show that first best public transport fare can decrease with travel distance in radial corridors, if in the peak direction (toward the CBD), passengers that travel shorter distances get on trains when more passengers are already on board, which represents a greater social cost. This inverse relation between fare and travel distance might not hold if we consider that long-distance passengers yield greater discomfort externalities than short-distance passengers due to crowding and standing externalities ([Kraus, 1991](#), [Hörcher et al., 2018](#)). Because in metro systems, dwell times are much more standardized than in buses service, the delay effect is usually negligible compared to the crowding externality, so distance-based fares are likely to be more efficient in the case of metro lines.

In practice, subway systems that have zonal or distance-based fares reflect that longer trips also have a larger marginal operator cost, as commonly done in Europe. At the same time, there are plenty of subway systems with flat fares for single trips, regardless of trip length, which can be based on simplicity or on equity grounds, in those cities where lower income households are concentrated in the outskirts, pushing them to travel longer distances for work. The latter is an argument put forward in some Latin American cities to have flat fares in subway systems.

Externalities

Mohring Effect

Subways systems are designed to accommodate a large number of users, which allows benefiting from substantial economies of scale when facing sufficient demand. This includes economies of scale on the supply side, as well as on the user costs. To illustrate, consider that if an increase in demand is met with an increase in supply (service frequency), average waiting time cost is reduced for each user. The average user cost therefore decreases with patronage, a phenomenon often called the Mohring effect. Empirically, the Mohring effect is found to justify subsidizing public transport. Yet, as patronage of the subway line increases the various forms of public transportation congestion (in-vehicle, on platform for boardings and alightings), this leads to a partial or full mitigation of the Mohring effect (see [Section Subsidies and Values Capture](#)).

Crowding

Crowding becomes an increasing concern in several subway networks across the world. As public transit use intensifies as a result of population growth or transit oriented policies, the number of users within each train (in-vehicle density) and on the platform increase. On the most congested lines, large queues may develop during the rush hour within or even outside the subway station.

These phenomena negatively affect the user experience in several ways ([Tirachini et al., 2013](#)). First, crowding implies discomfort as some users become unable to sit. Users, seated or standing, may also be hindered in their activities (reading, using their mobile phone, etc.) if other users are too close. Excessive proximity may also generate anxiety, or accentuate the perception of risk to personal safety and security. These cause the value of travel time savings (VITS) to increase with the crowding level. For instance, [Whelan and Crockett \(2009\)](#) find that the VITS of a sitting (standing) passenger increases by a factor 1.00–1.63 (1.53–2.04) as in-vehicle density rises from 0 to 6 pax per square meter. Additionally, crowding also increases travel time as it leads to longer boarding and alighting times, or even waiting times when users must wait for the next train.

The economic cost of crowding is accordingly substantial for heavily used subway networks. In the case of Paris, [Haywood et al. \(2018\)](#) find a marginal external cost of 0.123€ per passenger – kilometer at rush hour, resulting in a welfare loss of approximately 65 M€/year. To mitigate this cost, subway network managers may resort to several strategies. First improving frequency, including through the automation of the line which allows higher frequencies and makes it less costly to do so. The vehicle design may also be enhanced to increase the available floor space and the number of seats through communicating cars or double-decker vehicles. Finally, travel demand management policies such as crowding-dependent pricing ([de Palma et al., 2017](#)), alternative work schedules or passenger flow control may be used to regulate demand.

Reliability

Unreliable travel times cause travelers to arrive earlier or later than expected at their destination, which is a major source of discomfort as shown by the travel behavior literature. Thus, modal reliability is a key factor that travelers consider when making basic travel choices, such as decisions regarding mode, route, and departure time. How predictable travel times are make a mode more or less reliable. The literature on travel time variability usually shows that subway systems are more reliable than motorized road-based modes such as buses and cars, when these are subject to congestion ([Durán-Hormazábal and Tirachini, 2016](#)).

Conclusion

Subway systems deliver unparalleled performance in high-capacity transport provision. Their efficiency might further increase due to numerous efforts aiming at standardizing subway constructions and operations. Under regular conditions, it is anticipated that the global growth of subway ridership and the expansion of the number and coverage of subway networks will continue, fueled by urbanization. The ongoing global health crisis imposes new challenges on the industry, however. With social distancing rules, the full potential of mass rail transit cannot be exploited, and a general shift in urban lifestyle, including more remote working, may jeopardize subway demand anyway. This imposes a short to medium term financial threat on operators, especially on the ones operating mature networks that require substantial renewal expenditures. Eventually, the future of subways is closely linked to the prevalence of the densely populated city model of the early 21st century. Assuming that physical proximity will remain a major requirement for the productivity and competitiveness of cities, it is unlikely that other transport modes will ever be able to reach the efficiency of underground rail technology.

Introduction

In every state, the need and importance of rail transport differ. Nowadays the rail transport sector faces competition from air, road, and water transport. However, rail transport remains relevant and attractive today. One of the objectives set out in the White Paper adopted by the European Commission in 2011 is to increase the volume of rail freight and passengers ([White Paper, 2011](#)). Seeking to achieve the results in the rail transport sector the management of the railway undertakings has an essential meaning. It should be noted that each country has a substantially unique rail transport practices, for example in one country are more widely developed passenger transport services and in other—freight transport services. In view of these characteristics, a specific management strategy for railway undertakings should be selected and implemented accordingly.

The rail sector has been undergoing reforms in the world for decades, which concern the management of railway undertakings. However, it should be borne in mind that the experience of reform varies, both in terms of the reform models chosen and the consequences for the appropriate implementation of the model. In the United States, for example, there has been a shift from a heavily regulated environment to a less regulated one, while the emphasis in the EU is not on deregulation, but rather on greater harmonization between the Member States and on the goal of creating more competition—this is a trend that can be seen in other countries around the world ([Finger and Künneke, 2011](#)).

The EU requirements in this area are of particular importance when examining the management of railway companies in the Member States. One of the cornerstones of the EU is to open up the markets of the Member States and ensure the development of fair competition between them. On this basis, common guidelines, rules to ensure that these objectives are achieved, are being developed in the rail transport sector. Member States are complying with their obligations when implementing the rail transport packages adopted by the EU:

1. The first railway package was adopted in 1998. The package, consisting of three directives, provided all railway undertakings licensed on the basis of community criteria with equal and nondiscriminatory access to the railway infrastructure in order to offer services in all Europe. The package has led to a major overhaul of the sector's legislation to ensure its integration into the European area and to allow it to compete with other modes on the most favorable terms.
2. The second railway package, covering three directives and a regulation, adopted in 2004, provided for a wider opening of the freight market, promoting liberalization and harmonization of technical standards.
3. The third railway package, consisting of two directives and two regulations, was adopted in 2007. It provided for the full opening of international passenger services as well as for the licensing of railway drivers, rail passengers' rights regulation, etc.
4. The fourth railway package, consisting of three directives and three regulations, was adopted in 2016. One of the main aims was to create a single market for railway services. This package is relevant to the subject under consideration as it lays down requirements for the management of railway undertakings.

Prior to the adoption of the last fourth railway package, it was considered that it would require the complete separation of the infrastructure manager from the provision of services. However, the fourth railway package allowed for a vertically integrated management structure, allowing the infrastructure manager and rail transport services to be combined, but only within the strictly so-called "Chinese walls", ensuring legal, financial, and operational separation ([House of Commons Transport Committee, 2012](#)). The purpose of such EU regulation is to ensure that the infrastructure manager is independent and financially separated from the railway undertakings by performing essential functions (such as allocating public railway infrastructure capacity).

This chapter is structured as follows: the second section describes the management models, the third section analyzes the comparison of the models and the last section presents our conclusions.

Management Models

Models of railway management are essentially singled out according to the relation between the management of public railway infrastructure and the provision of rail transport services. On that basis, two models can be singled out ([Gomez-Ibanez, 2006](#)):

1. Separated management model (vertical separation) where the infrastructure manager is separated from railway services (Sweden, Great Britain).
2. Integrated management model (vertical integration), based on the holding principle, where the infrastructure manager and the railway undertakings are parts of the same organization (Germany, Italy).

A fully integrated management model can be distinguished as a form of integrated management where the infrastructure manager and the railway service provider (carrier) are one and the same undertaking. Such a model existed in many European countries before the reforms of railway companies (Lithuania) and is based on the monopoly principle.

It is noteworthy that the EU is unique in that it seeks to separate infrastructure manager and rail transport services in order to ensure nondiscriminatory conditions for railway undertakings. In other parts of the world, different models prevail, such as:

- In Japan railways have a vertically integrated structure. The companies generally own their rolling stock as well as the infrastructure on which they operate.
- In the United States, most rail networks are owned by private freight carriers. However, long-distance passenger services operated by Amtrak (effectively owned by the government) are mainly carried on lines owned by freight carriers or government agencies ([Williams Rail Review, 2019](#)).

Separated Management Model (Vertical Separation)

The management of British and Swedish railway companies are the most frequently analyzed examples of vertical separation. Models from these countries are a frequent subject of evaluation to see if a real separation between infrastructure and services can achieve greater efficiency in the rail sector.

The British Rail industry has undergone a number of reforms. The privatization process in Britain between 1994 and 1997 saw the dismantling of “British Rail” and the separation of public rail infrastructure and rail transport services. Ownership has largely gone to the private sector. At the time of privatization, the private company Railtrack became the owner of the rail infrastructure network. Later Railtrack was transformed into the railway administration and “Network Rail” (NR). NR was founded at the time as a private company, but in 2014 NR was retrained into a public sector body. At the time of privatization, “British Rail” passenger train fleet was transferred to private rolling stock operating companies (ROSCO). ROSCO owns most of the rolling stock and leases it to the companies operating the trains. British Rail freight trains have been sold to freight carriers—English Welsh and Scottish, freightliner and others.

Currently, the rail sector in Great Britain includes the infrastructure manager, NR, the independent economic and security regulator, the Office of Rail and Road, and passenger and freight services provided by private railway companies. Most of them are subsidiaries of railway companies such as Deutsche Bahn (German national rail operator), SNCF (French national rail operator), and ND (Dutch national rail operator).

The main features of today's railway management in Great Britain are as follows:

- The network infrastructure is state-owned and operated by NR, which has one shareholder, the Secretary of State for Transport. The network is operated and maintained through the setting of access charges and the subsidies to NR.
- The majority of passenger train services are provided through publicly established franchise agreements. In addition to franchising, there are few private passenger carriers on the network. These operators do not have a contract with public authority and provide a very small proportion of passenger transport services.
- Freight carriers are private sector companies. Access charges are payable to NR.
- Most of the British fleet is owned by the private sector ROSCO and leased to train operators for the duration of the franchise agreements.
- The Office of Rail and Road plays an important role in regulating NR and train operators. The role of the bureau includes independent safety regulation, ensuring access rights that NR offers to its customers (operators of passenger and freight services), etc. ([Williams Rail Review, 2019](#)).

One of the foundations of the reforms in Great Britain was the conviction that private ownership and management is better than public ownership, as private companies are better able to ensure that market needs are met for maximum profits. For example, this explains why even public rail infrastructure has been privatized ([Alexandersson and Hulten, 2006](#)). It should be noted, however, that infrastructure has subsequently returned to the hands of the state, and that privatization of infrastructure has often been seen as a mistake of the reforms in Great Britain and an example to be learned by other countries.

Another country where the separation between infrastructure manager and services was also implemented is Sweden. A reform of the railway sector in Sweden was initiated in 1960 with the aim of liberalizing the market and creating conditions for competition. The Swedish State Railways (SJ) was a state business administration with a monopoly on freight and passenger rail transport, completely isolated from competition. However, SJ was in difficulties and it was necessary to reform the railway sector. The state has

faced problems such as the reduction in passenger numbers due to the use of private cars, the closure of passenger lines, etc. In 1988 The Transport Policy Act separated rail infrastructure from rail transport services. The new state-owned company Banverket became fully responsible for infrastructure and maintenance investments, and SJ was transformed into a service provider paying access fees. In 2000 the Transport Policy Act changed SJ organizational structure into several companies focusing on different sectors of the railway: SJ (Passenger Division), Green Cargo (Cargo Division), Jernhusen (Real Estate Division), EuroMaint and SweMaint (Service Department), TrafficCare (Cleaning Services), and Unigrid (Computer Information System Division). In 2007 TrafficCare, Unigrid, EuroMaint, and SweMaint have been privatized. Legislation was subsequently amended to bring the legal framework into line with the EU requirements. In order to improve infrastructure management, Banverket was merged with Vagverket Road Administration and was formed Trafikverket to improve infrastructure management.

The main features of today's railway management in Sweden are:

- The national authority Trafikverket owns state railway infrastructure (80% of the railway lines).
- Most railway stations are owned and maintained by Trafikverket.
- Jernhusen, state-owned real estate firm, owns station buildings.
- EuroMaint and SweMaint provide maintenance services.
- Train Traffic control, a traffic management unit, in conjunction with Trafikverket monitors all train movements on the Swedish rail network.
- The Swedish Transport Agency is the regulatory body responsible for safety issues, permits, etc.
- State-owned Green Cargo is the largest freight carrier, accounting for approximately 70% of the market (Alexandersson and Hultén, 2011).

In Sweden recurring problems were key drivers of reform seeking to make SJ profitable. SJ problems were due to the high level of competition from other modes of transport, and the main aim of the reforms was to improve rail's ability to compete with other modes of transport. This was a key objective of the 1988 reform. Another important factor was the maintenance of unprofitable lines for social use. However, the reform process in Sweden was gradual compared to the more radical measures implemented in Great Britain (Alexandersson and Hultén, 2006).

Integrated Management Model (Vertical Integration)

Germany has implemented integrated railway management model. In Germany the infrastructure manager and the railway services providing companies are separated—they have separate accounts and boards, but are accountable to the holding company—Deutsche Bahn AG (DB AG). Alongside the vertically integrated companies of DB AG, the market is also served by private freight and passenger transport companies. Reform in Germany began in 1980 and DB AG was transformed into a holding company in 1999. Both DB AG and private operators have the right to negotiate access to the infrastructure and to require access to other facilities owned by DB AG companies such as DB Station Service, DB Energie, etc.

The main features of today's railway management in Germany are:

- Infrastructure in Germany is managed by subsidiaries of DB AG: DB Netze Energy, DB Netze Stations, and DB Netze Track. DB Netze Energy is responsible for supplying all types of energy to DB AG and other private companies. DB Netze Stations' activities include the management of passenger stations, transport stops, as well as the development and marketing of train stations. DB Netze Track is a subsidiary of DB AG, which includes other companies:

DB Netz AG is responsible for railway infrastructure. Its activities include the ongoing maintenance and development of infrastructure, as well as cooperation with railway undertakings in the preparation of train schedules, maintenance and repair of the railway network.

DUSS GmbH is responsible for transshipment terminals owned by the infrastructure manager DB Netz AG and third parties.

DB Fahrwegdienste GmbH is responsible for risk management and logistics.

DB RegioNetz Infrastruktur GmbH is responsible for the organizational management of its railway lines and stations. It owns regional railways with some 13,000 railway tracks.

- Cargo transportation is provided by DB Cargo AG (with a Europe-wide freight presence with 16 subsidiaries in different countries) and DB Schenker (integrated logistics services)
- Passenger transportation is provided by DB Long-Distance (domestic and international transportation), DB Regional (domestic passenger services), and DB Arriva (international passenger services).
- DB Services is a service segment that combines six different sectors: DB Vehicle Maintenance (inspection and maintenance, modernization and train maintenance), DB Systel (IT and telecommunication service provider), DB Services (facility management and industrial services), DB Fleet Management, DB Communication Technology (maintenance and repair of IT and network technologies), and DB Security (security function).
- Bundesnetzagentur (BNA, a regulatory body for services such as electricity, gas, telecommunications and postal services), since 2006, became responsible for overseeing the rail market. The mission of BNA is to ensure nondiscriminatory access to rail infrastructure.

It is to be appreciated that the implementation of an integrated management model may facilitate the planning of infrastructure investments and railway operations in the country. In addition, it is possible to have a generally compatible tariff policy throughout the network and eliminate or minimize any contracts with other companies. This means that vertical integration helps optimize the entire system, what is quite hard to do with a vertically separated management model (Pittman, 2007). However, it is noticeable that the German model faces certain problems due to the close relationship between infrastructure management and service provision. In the case of Germany, the DB holding structure is quite confusing, making it difficult, for example, to trace cash flows between holding companies, which may lead to an under-enforced EU requirement for financial transparency (Nigrin, 2014).

It should be noted that as a form of integrated management a fully integrated model can be singled out. It is a traditional model of the organization of railway management in which a single public entity controls all or most of the infrastructure, as well as the freight and passenger services sectors, and performs administrative functions. Several countries are still using this mode—it is more common outside Europe, for example, clearly visible in China and India. There are also remaining countries in Europe that use fully integrated model. For example, Lithuania has a fully integrated management model where the infrastructure manager and the service provider are structural units of the same company. However, it was decided to reform the Lithuanian railway sector and move to a holding structure. This choice was determined by the fact that Lithuania is one of the few states with the only state carrier operating in the railway transport market. In order to comply with EU requirements, it was decided to reform the management of railways. In Lithuania it was decided to follow the example of Germany and to entrust the functions of infrastructure manager, freight, and passengers to the newly established subsidiaries of AB Lietuvos Geležinkeliai. In this way, AB LG Infrastruktūra will perform the function of the infrastructure manager, AB LG Cargo will carry the freight and AB LG Passengers will carry the passengers.

The main argument why full integration (state monopoly) can be beneficial is that the services provided, the condition of the railway infrastructure and rolling stock and other technical aspects are planned and organized together. Instead of distributing planning, operations to multiple organizations, all decisions can be made within a single company (Van de Velde et al., 2012). On the other hand, such a monolithic structure leads to a lack of competition, making it difficult for such a monopolistic company to improve the efficiency and productivity of the industry. In addition, as with most government-controlled industries, profitability goals are often complicated by set social goals (Finger and Künneke, 2011).

As mentioned earlier, the main goal of the reforms is to create a single railway market in the EU. According to the European Commission's Sixth report on monitoring development of the rail market, in 2016, new operators competing with incumbents were operating in all Member States except Greece, Ireland, Lithuania, and Luxembourg. This means that these countries probably did not properly implement the requirements of EU, as their markets are still closed. It should be noted that the European Commission monitors the transposition of the Directives by the Member States. In the event that a Member State is suspected of not transposing or transposing incorrectly the Directive, the European Commission shall send a letter of formal notice to the Member State. If the European Commission decides that the Member State is not fulfilling its obligations correctly, the European Commission shall send a reasoned opinion requesting the implementation of its obligations. If, in this case too, the State does not comply with the requirements of the European Commission, the European Commission has the right to apply to the Court of Justice. For example, in January 2019, the European Commission sent a letter of formal notice to Greece and Ireland requesting information on the transposition of Directive 2016/2370/EU (Fourth Railway Package). The Member States did not reply to the European Commission within the deadline of two months and were therefore given a reasoned opinion on July 25, 2019. If the Member States are found to have failed to comply with the requirements of the Directive, the European Commission will be entitled to apply to the Court of Justice.

Comparison of the Models: Advantages and Disadvantages

Europe has faced a number of challenges in implementing rail reforms. Problems had to be solved, such as encouraging changes in the major historical operators, improving the supply of rail transport, the creation of cooperation and competition between market players. The rail systems of the European countries are very different in terms of services provided and in terms of technical parameters. For example, freight transport is more developed in Eastern Europe, while Western Europe is more specialized in passenger services. Among other things, technical parameters such as track gauge, signaling systems are different in the countries and this makes it difficult to reconcile national railway systems. For these reasons, the EU is seeking coherence and harmonization between the different systems of Member States.

The European Member States have an opportunity to choose which management model they would like to implement. The Community of European Railway has expressed the view that it is unrealistic for a single model to be applicable to all European countries, so every country can choose the most appropriate management model (Bodiroga-Vukobrat et al., 2016).

The appropriate choice of model is influenced by national characteristics, such as the well-established management practices of the national railway undertaking, the need for rail services and the level of development of the railway sector. Reforms also take place depending on the separation of infrastructure from services provided and the level of privatization. For example, in countries such as the United States, Japan or New Zealand, companies remain vertically integrated. In Europe, the general trend is to separate infrastructure management from passenger and freight services (Gomez-Ibanez, 2004).

The primary objective pursued by the states in the implementation of their chosen railway management model is efficiency, that is, to maximize the potential available and to derive maximum benefit from it. A number of studies have been carried out to determine which of these models is more effective and could help to improve competition in the market, to reduce costs or to meet

the needs of customers using rail transport. As a result, the various studies in this field are quite difficult to interpret, since different criteria are used to evaluate efficiency. In addition, the same model is implemented differently in each country, so only the main features of the models can be singled out.

As a general rule, states begin to consider the implementation of a separated management model that could encourage private sector involvement in the provision of train services. However, this choice is perceived as complex and “bold” in the sense that it is necessary to define precisely the responsibilities and accountability between the railway infrastructure manager and the train service operators. States that consider the implementation of a separated management model often reject it as too complex or endangering some of the integration benefits, such as being closer to the end customer, coordinating public rail infrastructure, managing emergencies, etc. (World Bank, 2017). The choice of a separated management model poses greater challenges for the state as it loses control over the provision of services that could be maintained by an integrated management model.

However, in countries that have opted for a separated management model, can be singled out some prevailing trends and benefits of the model. From a competition standpoint, one of the major advantages of vertical separation is that it ensures a level playing field between different operators when no operator has more control over the infrastructure than others (Haylen and Butcher, 2017). A separated management model can be considered when it is seeking to protect nondiscriminatory access to rail infrastructure as the charging or capacity allocation body of an integrated railway undertaking seeks to favor its own carrier, while an independent infrastructure manager will normally seek commercial benefits and has an incentive to satisfy applications from both new and established carriers (Directorate General for Internal Policies, 2011). It is appreciating that the clearest way to avoid discrimination in access to rail infrastructure is the institutional separation of rail activities from rail infrastructure (Merkert et al., 2008). Thus it is noticeable that the development of competition is more established in countries that have opted for a separated management model than in countries where reforms have been limited. This confirms that a separate management model, combined with a strong regulatory body, can be an effective measure of ensuring nondiscriminatory access to rail network.

The advantages of a separated management model include greater separation between private and public interests, clear and unambiguous conditions for the use of railway infrastructure and economic clarity in the rail transport sector. An important consideration here is the ability to take greater account of customer needs, as business is better able to respond to market demand than monopolistic railway companies (Profillidis, 2006).

From the point of view of the provision of specific services, the transfer of services from the state to the private sector improves market and commercial performance, especially in the freight sector. However, privatization of the rail network has proved less attractive in countries where national railways have a strong passenger transportation base (World Bank, 2017). It is appreciated that the separation of passenger services from infrastructure management activities is less beneficial, as passenger services are generally heavily dependent on public funding (Directorate General for Internal Policies, 2011). Studies have even shown that a separated management model can significantly weaken railways in passenger transport sector rather than strengthen them (Laabsch and Sanner, 2012). This implies that a separated management model can be more useful and efficient in countries where rail transport is more used in freight transport. However, other studies and a broader analysis of the impact of vertical separation on the market have shown that there is no substantial link between vertical separation and rail freight or increased rail freight traffic overall. If the primary objective is to promote the efficiency and growth of rail freight, vertical separation may even undermine rail development in certain circumstances, especially in some Central and Eastern European countries that do not have adequate infrastructure funding (Drew and Nash, 2011). This could, for example, be the result of high infrastructure charges, which would prevent new railway undertakings from entering the market and launching their services, thus even a separated management model would not help to occur competition in the market.

The argument against a separated management model and the choice of an integrated model is that in some parts of the world (e.g., United States) railway may be the owner of the infrastructure and this in itself does not prevent other operators from entering the market after paying appropriate fees. Competition can exist without separation. But separation can be a catalyst for competition and for facilitating the entry of other rail operators (Profillidis, 2006).

One of the great advantages of integration is the cost reduction. For example, empirical studies of railway companies from 27 European countries between 2000 and 2004 found that integrated companies can achieve greater productivity through economies of scale, whereas with a separated management model, states may face increased costs (Growitsch and Wetzel, 2009). However, the integrated management model has received considerable criticism for restricting competition. For example, incumbent freight operators can exploit their market position and this may lead to conflicts of interest in areas such as access to terminals and other facilities, train path allocation, maintenance of rolling stock, etc. (The European Court of Auditors, 2016).

Politicians and rail administrations in various countries are therefore weighing the advantages and disadvantages of vertical separation to determine whether this type of reform is an appropriate way to improve the performance of their rail sector. Despite various structural and property reforms carried out around the world, there is no clear model for achieving this goal of increasing competition and efficiency (OECD, 2006). It is difficult to evaluate different models between countries, as the results may vary depending on different factors. However, it is important to understand that separation may be more beneficial in some industries than in others (Pittman, 2005). For example, it was found that full separation between infrastructure and services is not a prerequisite for improving rail efficiency (Friebel et al., 2003). Among other things, later studies concluded that railways are quite sensitive to reforms and that applying a single model to all countries is certainly not a good option seeking rail efficiency (Friebel et al., 2008). Consequently, the main step that all countries must take implementing the relevant model is to evaluate the priority areas for rail transport activities and define the results to be analyzed on the basis of examples from other countries.

Summary and Conclusions

Thus now it is possible to single out the prevailing tendency in the practice—the states are at the stage of implementation of the chosen management model. Following the example of these countries, it is possible to analyze how they are achieving their goals by implementing the management model chosen, what are the advantages and disadvantages of a particular management model. It should be noted that the fundamental objective of the reforms is to achieve the highest possible level of efficiency in the railway sector, therefore the assessment of the efficiency of the chosen model is based on calculating the costs incurred, analyzing changes in competition in the markets, etc. Although the various studies conducted do not provide a firm answer to the question which model is more effective, the main features and trends dictated by the implementation of the model in the selected countries can be singled out. A separated management model can help the state improve competition in the market, while an integrated management model may expose new market players to discriminatory conditions. Among other things, a separated management model enables the market itself to refine what services it needs, for example, freight services or long-distance passenger services. The integrated management model has more advantages in terms of control of public railway infrastructure and gives more guarantees to the users of passenger services.

Introduction: Current Regulatory Scenarios in the Rail Industry

As in other transport modes, the regulation of the provision of infrastructure and rail services is closely determined by the degree of vertical integration and the overall opportunities for competition “on the tracks” and “for the tracks” that are feasible in each particular market. However, some additional features, such as the multiproduct nature of this activity, the presence of indivisibilities in inputs and outputs, the role of rail transport within the public service network, or the existence of externalities, make regulatory tasks in this sector particularly interesting for the transport system as a whole (Bitzan, 2003).

With few exceptions around the world, from its birth in the mid-19th century to the last decades of the 20th century, the most widespread market structure in the railway sector has been that of a single state-owned company, responsible for the integrated management of both infrastructure and services. Although there were some differences in their degree of commercial autonomy, the regulation and control of these companies were relatively homogeneous: traditional price and service regulations were widely assumed to protect the general interest, and there was an explicit obligation on the part of the companies to meet any demand at those prices: closing existing lines or opening new services required government support. Thus, competition was perceived almost as an oxymoron and even discouraged, while the preservation of the public nature of industry was seen as the key regulatory principle.

Under this protective environment, these national companies progressively lost any connection with market forces and were characterized by increasing losses (usually financed by public subsidies) and business decisions mainly oriented toward production targets rather than commercial objectives. As a result, most railways were in a very weak position to face fierce intermodal competition in their provision of freight and passenger services, and it was clear that a profound restructuring process was necessary to guarantee the survival of the sector. The changes started in the 1980s and were aimed at improving the sector performance by introducing or strengthening competition. The most salient characteristic of the restructuring processes was the consolidation of alternative organizational structures for the industry which, in turn, defined new regulatory scenarios. These structures differed along two main dimensions represented in Fig. 1: the extent of vertical separation introduced after the changes and the amount of private participation allowed in the industry after the reforms.

With regard to the first dimension, the existence of substantial (and sub-additive) fixed costs, as well as the presence of notable indivisibilities in their operating assets, has led economists to consider the provision of rail infrastructure as one of the few remaining textbook examples of a natural monopoly. Unlike the provision of services—where different forms of competition are more feasible—regulation of rail infrastructure remains more necessary, specifically requiring efficient pricing rules, clear access rights, and sound investment criteria for its long-term development. Indeed, after the restructuring, each country addressed this relationship between infrastructure and services in a different way: many chose to keep infrastructure in public hands, creating dedicated agencies to regulate (public or private) train operators; others established nominally independent (but state-owned) companies to manage stations and tracks, whereas only a few completely privatized infrastructure and/or operations, with or without unbundling them first.

The vertical axis in Fig. 1 summarizes the three main options for the vertical restructuring of the railway industry and provides several examples in different countries. The first option (*vertical integration*) corresponds to the traditional rail model (which still exists, e.g., in India), where a single (public) operator controls all infrastructure facilities as well as the provision of freight and passenger services. The *competitive* (or open) *access* model is characterized by the coexistence of an infrastructure manager (usually in the hands of the government), which is required to make it available to other operators (including public firms) on a fair access basis. This model—common in several European countries with minor differences across them—retains the advantages of integration, but its overall effectiveness may be compromised in the absence of supervision by competition authorities to avoid discriminatory practices. Under the *complete vertical separation* model, the management (and, possibly, the ownership, as in the United Kingdom) of

Figure 1 The rail restructuring process: examples. Source: Own elaboration, adapted from Campos (2008).

the infrastructure is fully separated from services, and the manager is not allowed to provide transport services. This option promotes the entry of private operators and competition “on the tracks” or “for the tracks” (through tendering mechanisms) may emerge. However, the unbundling may also entail a number of disadvantages for the rail industry. The main one is the loss of economies of scope that are obtained from the joint operation of infrastructure and services. There is also a greater risk that the unbundled network will be less attractive for the users as compared to alternative transport modes and it should be noted that vertical separation also requires more complex institutional arrangements, with higher transaction costs and, sometimes, less investment incentives, due to higher regulatory risks. In some countries, the potential conflict between sectoral regulators, competition authorities, infrastructure managers, and rail services operators is unescapable. Its resolution often requires a clear definition of the competences of each party and a reinforcement of the independence of the supervisory bodies.

Regarding the privatization dimension, the horizontal axis in Fig. 1 provides an orderly list of the main models found on railways around the world after their restructuring processes. The first one corresponds to *government’s direct rule*, where the industry is still controlled by one or more Cabinet departments (e.g., the Ministry of Railways in India). The second case refers to the existence of one or more *state-owned firms* in the sector (as in China, Israel, or several European countries), with some degree of commercial autonomy, but still requiring government approval for most investment and pricing policies, as in the traditional model. In some countries, this ownership model is often completed with other forms of public–private partnership, including *contracts* for outsourced activities, for the *management* of infrastructure or services, or even the *leasing* of specialized assets, such as locomotives or wagons. The use of tendering mechanisms, such as *concessions* (franchises or licenses), constitutes one of the most popular methods to introduce private participation in railways, particularly in some European and South-American countries, and, finally, *total privatization* is less frequent in this industry, although private operators have existed for many years in countries such as the United States or Japan.

After this introduction, next section provides a review of the most relevant regulatory issues after the reforms, particularly focusing on the need of regulation itself and how to achieve its objectives. This paper concludes with a brief summary and conclusion.

Relevant Regulatory Issues in the Rail Industry After the Reforms

The two-dimensional post-restructuring space presented in Fig. 1 defines a new institutional environment for the rail industry whose most relevant feature is the diversity of regulatory scenarios that have emerged in different countries around the world (see Nash et al. (2013) or Laurino et al. (2015) for details). Most of these scenarios, however, share a number of similar concerns about prices, cost recovery, access to infrastructure, and quality regulation.

When (and How) Should be Regulated Rail Services?

In countries where there exists private participation in freight or passenger markets, the nature of price regulation has changed as compared to the traditional rail model: instead of simple price-setting rules for rail services, regulation has progressively become a price-supervision process intended to avoid market dominance or other uncompetitive practices. This process is generally designed

according to two factors: the degree of market power effectively enjoyed by the operators and the existence of other limiting factors, such as intermodal competition. This latter element is relevant in freight services (intermodal competition from trucking) and high-speed services (in competition with air transport), but in the case of commuter and regional routes, social pressure to keep fares low may affect price interventions. In practice, the most common instruments for price control in these cases adopt the form of a rate of return regulation or a price cap mechanism.

Rate of return regulation is commonly used in Canada, Japan, and the United States. Its objective is to set prices so that the regulated operator only earns a fair rate of return on its capital investment. The regulator typically determines a revenue requirement based on the estimated total costs during a test year, and an estimate of the cost of capital for the firm, given by a “reasonable” rate level multiplied by an asset base. In spite of this simplicity, this type of price regulation is often criticized in railways on the grounds that it offers little efficiency incentives, since firms can pass production costs on to final users in the form of higher prices. In addition, it often leads to overinvestment in capital (Averch–Johnson effect).

As a price-control alternative, many European countries have opted for cost-plus incentives whose main aim is the achievement of dynamic efficiency by sharing its gains between the producer and the regulator. In its most standard form, it consists in setting a maximum price scheme based on long-run marginal costs in order to provide the train operator with an incentive to minimize costs by keeping all or part of the gains associated with the firm's increases in efficiency. This mechanism emerged as a consequence of the criticism directed at the lack of cost minimization incentives embedded in the rate of return regulation and other traditional price regulation mechanisms. However, its efficiency gains have to be balanced with the higher informational requirements that it implies.

There are a number of minor variations of the price cap system currently applied in the rail industry. One of the most widely used is the RPI-X formula. In this setup, the price for a basket of the firm's prices may increase in any one year by no more than the increase in the retail price index (RPI) for that year, minus some (efficiency related) X-parameter. In the case of multiproduct activities, such as railways services, this expression can be easily adapted by requiring that a certain weighted average of percentage price increases do not exceed the rate of growth of the RPI, less X percent. In the United Kingdom, for example, this mechanism has been applied to passenger traffic franchises. Commuter fares are regulated with respect to a basket containing all relevant fares, broadly weighed by the income that the operator derives from each of them.

How to Guarantee Cost Recovery?

A second regulatory issue is related to the recovering of infrastructure costs. Apart from a high ratio of fixed to marginal costs, the provision and operation of tracks, stations, and other rail infrastructure is characterized by the existence of avoidable and unavoidable costs. Avoidable costs are uniquely associated with a particular output: if it is not produced, no cost is incurred; therefore, avoidable costs may be considered as a floor to regulated prices (if any), since charging less than these costs is equivalent to operating at an economic loss. This makes standard pricing rules inoperable in this sector, since first-best or marginal cost pricing rules result in large deficits that jeopardize the long-run survival of the operator.

Another complexity factor is the existence of cross-subsidization problems when common costs are relevant. This can be illustrated with the case of a profit-regulated railroad connecting two large cities and also providing rail services to a smaller town along the route between the two cities. The fares charged from the small town generate revenues exceeding the additional cost of serving it, such as ticketing and station costs, but not enough to cover an equal or proportionate (however, defined) share of the common costs, such as trackage, signaling or trainyard costs. The issue is how to allocate common costs among customers and services. In many cases, cost sub-additivity and efficiency require joint production and allocation of fixed costs among all services, without cross-subsidization (accounting for externalities whenever present).

This is not only an equity problem, as in this example, but also a relevant issue for efficient pricing of infrastructure like railbeds, signals, or stations. The standard procedure in these cases is to rely on the so-called fully distributed costs method, under which common costs are allocated on the basis of some common measure of utilization, such as gross tons/km, or other measure of relative output or gross revenue. Alternatively, common costs can also be allocated in proportion to costs that can be directly assigned to the various services. The arbitrary nature of fully distributed cost methods and its lack of a conceptual foundation have been criticized, but they remain a useful measure for recovering common costs.

However, the treatment of the cross-subsidization problem should not be based on excessively rigid criteria, particularly in markets with few alternative finance mechanisms. The analysis should be made on a case-by-case basis, since, for example, stand-alone cost tests do not apply if railroads are not allowed to abandon nonprofitable facilities or services. If that freedom is denied, a railroad cannot earn adequate revenues if its rates on potentially remunerative activities are constrained by stand-alone cost ceilings.

The cost recovery principle should be a central issue in the design of any rail infrastructure pricing procedure. The theoretical and political debate focuses on two options. Many public firms still advocate the use of efficient pricing mechanisms and propose marginal cost rules with the simultaneous use of public subsidies to cover fixed costs. Alternatively, a growing literature suggests the use of full cost recovery prices, including price discrimination, multiple part tariffs, or cross-subsidization schemes, if needed. Although it is thought that it might yield inefficient outcomes, it constitutes the second-best available alternative in most cases.

With respect to infrastructure pricing, it is clear that in principle, track access charges should be based on marginal cost pricing rules. In practice, however, the use of these criteria is difficult due to at least three reasons: the cost structure of the rail network, which cannot always be recovered with simple pricing rules; the asymmetric information problem faced by the regulator with respect to

these costs; and the subsidy levels that can be sustained in the long run. Several econometric studies have shown that the marginal cost of rail operators that are still vertically integrated lies in the range of 60%–70% of average cost, whereas when services are separated from infrastructure, the marginal social cost of rail infrastructure alone often is well below the same range. Price discrimination, if feasible and politically acceptable, may help to raise cost recovery to around 60% of total cost without driving demand off the market. Thus, full cost recovery would require a further price markup of more than 60% above the efficient price.

Alternative proposals, in terms of the so-called Ramsey pricing principle, have been defended for infrastructures with high fixed costs and low marginal costs. However, they rarely work in practice, since they increase users' suspicions of unfair treatment and undue discrimination. Moreover, under Ramsey pricing rules, all unattributable fixed and common costs are apportioned on the basis of the services' demand characteristics. For these reasons, a reasonable conclusion is to advocate a balance between cost-recovery and efficient pricing rules, giving preferential treatment to one over the other according to the case. The issue remains unsolved and depends on how different countries have faced their access pricing problem.

How to Promote Competition?

Apart from cost recovery issues, access pricing may create additional regulatory concerns in vertically unbundled scenarios or under competitive or open access. The problem is common in network industries where a single, vertically integrated firm (either private or public) controls the supply of an essential facility (in this case, rail tracks or stations), restricting "downstream" competition. It is obvious that in these cases there are incentives for infrastructure manager to set prices high to raise rivals' costs, but it could also be the case in which the regulator sets access prices too low in order to favor the entrants.

Depending on the discretion allowed to the infrastructure manager, potentially distortive effects on access prices can be determined in several ways. Firstly, when infrastructure is still state-owned, the regulator can determine the price as an integral part of the access terms defined in a contract with one of several private train operators. Secondly, the regulator may allow the operators to choose from a menu of alternative regulatory schemes, usually related to incentive-based regulation mechanisms. Thirdly, the firm may have discretion over aspects of access pricing subject to some overall regulatory constraint, and, finally, the firm may have full discretion over the price and is only restricted by the competition authorities.

In all of these cases, there are two main approaches to setting access prices when the principles of cost recovery plus the normal rate of return are required. Firstly, some countries use cost-related charges, which are based on the optimal first-best principle of pricing according to marginal cost (considered the forward-looking long-run incremental cost). The higher the proportion of common costs, the more complex the principle. It is based on the so-called efficient-component rule, which determines that optimal access charge is equal to the direct cost plus the opportunity cost of providing access (given by the reduction in the dominant firm's profit). To compute these costs, the regulator has to consider economic depreciation (physical depreciation plus technological progress) and forecast future usage. The first problem to be solved is that of the actual value of capital assets: nominal value versus potential to generate cash. While the latter is clearly a function of the privatization and regulation methods and the extent of competition envisaged in bidding for the right to operate concessional infrastructure services, the former is more likely to reflect a past situation that domestic reforms are trying to overcome.

The second method of setting access prices consists of developing usage-related charges. Once-avoidable costs are covered by increasing prices that are inversely related to demand elasticity. Another option (less controversial) is the use of a two-part tariff to avoid service cuts by train operators to save charges even when the network has no cost saving. In any case, excessive infrastructure access charges may discourage new railway operators from entering the market. European Union rules, for example, require track access charges to be set on the basis of direct costs, namely the cost directly incurred as a result of operating a train service.

What About Quality Regulation?

Quality (including safety) performance is not neutral for the economic contribution of the rail transport sector to the social welfare. The particular level of quality achieved by train operators and particular features in regard to three main dimensions that broadly define quality in the rail industry (service, externalities, and investment) critically determine the value added by this transport mode. The first question that naturally arises is why quality regulation is needed at all in this industry, and to what extent this regulation relates to the standard price regulation mechanisms described in the previous section. Economic theory provides a well-known argument to answer these questions: real-world transport activities are characterized by market failures due to information problems. Ideally, with a large number of competitive rail transport operators and well-informed users, quality regulation requirements would be minimal, and low quality and less reliable rail companies would be driven out the market. However, since full information does not exist, markets cannot exert this disciplinary role and competition may result in unsafe, unreliable, or unpleasant services. In the traditional model of the rail industry some years ago, price-quality adjustment problems were frequent, since the monopoly's optimal level of quality may not have coincided with social standards. Simple price regulation is seldom a solution. Any regulated, multiproduct monopolist in an environment of asymmetric information tends to degrade quality in order to achieve higher profits once it enters the market. Railway firms are not immune to this temptation, for example, in terms of punctuality and cancellation standards. The quality outcome of any monopolist, not only in the rail sector, heavily depends on the specific regulation mechanism. For example, with rate of return regulation, overinvesting in non-required technological quality may accentuate the Averch–Johnson effect. Alternatively, with price caps, a subtle quality reduction can be a very tempting way to cut costs. Therefore, the price regulation mechanisms analyzed earlier are considered incomplete if they do not include quality provisions. This is not always easy, since

adjusting price mechanisms by quality may render them inoperative or excessively difficult for the operators to manage or the regulator to monitor. Therefore, most regulators set quality standards or targets for train operators instead of correcting price control mechanisms. The use of yardstick competition or regulation by comparison is common in many countries (such as in Australia).

Summary and Conclusion

Declining traffic volumes, increasing intermodal competition and historical inefficiencies of the sector have entailed the need for rail market reforms over the last decades. With the aim of guaranteeing the long-term survival of the sector by making it face the forces of competition, the rail restructuring process is still very much in progress in many countries. Two key dimensions—perceived as major obstacles before the changes—have been addressed: the vertical integration of the industry, where only infrastructure may now retain a justifiable natural monopoly role, and excessive public sector intervention, which has been reduced through the progressive introduction of private rail operators. In this new context, the main roles of railways regulation should be to focus on setting charges level and structure to ensure cost recovery, manage conflicts, and avoid unfair practices over infrastructure access and, in general, to create a level playing field which ensures fair competition “on the tracks” and “for the tracks.”

Introduction

The term “railway” or “rail” encompasses terrestrial mass transport systems, on which trains move, either on their own or with the use of remotely transmitted power, on a dedicated steel way corridor (for a small number of metro lines and for many cases of driverless railway systems (cable propelled and self-propelled) of low/medium transport capacity, rubber-tyred wheels are also used.) defined by two parallel rails (Pyrgidis, 2016). From a transport system point of view, it is by default considered to be comprised of three (3) constituents:

1. railway infrastructure
2. rolling stock
3. railway operation

The term “rolling stock” refers to all rail vehicles moving on the dedicated corridor of the system and which either directly or indirectly facilitate railway transportation (Pyrgidis, 2016).

This article aims to classify rail vehicles based on three levels of integration within a wider railway system. Specifically:

- as an individual vehicle
- as part of a trainset
- as rolling stock for a specific category of railway system

This approach was deemed appropriate, since the choice of technical and operational characteristics of vehicles is often made on the basis of the trainset of which they are a part or of the system in which they are called to operate.

Alternatively, considering the classification of “rolling stock” (as previously defined) rather than a narrowest sense of the “rail vehicle,” the following three criteria for rolling stock high-level classification could be adopted:

- Based on function, namely power, trailer, and self-propelled (railcars and trainsets) rolling stock.
- Based on type of use, namely passenger rolling stock, freight rolling stock, and engineering vehicles.
- Based on the type of services for which the rolling stock is made, namely intercity trains (high or conventional speed), suburban trains, urban trains, rolling stock for steep gradients, and freight trains.

The aforementioned categories of rolling stock could be further classified on the basis of their technical and operational characteristics at a secondary level, in manner similar to the one proposed for categorization adopted for rail vehicles.

Based on the above, this article is structured as follows. Individual Rail Vehicle Classification Section provides an overview of individual rail vehicle classifications. Specifically, Elementary Classification Section provides a high-level or elementary classification, Secondary Classification Section provides a secondary level classification, and Classifications by International Union of

Figure 1 Rail vehicle elementary classification. Source: Modified from Pyrgidis, C., 2016. *Railway Transportation Systems - Design, Construction, and Operation*. CRC Press, Boca Raton.

Railways (UIC) Section presents a classification as proposed by the International Union of Railways. Definition and Classification of Trainsets Section provides a classification for “trainsets”. Railway Transport Systems Classification Section includes, in 1 Elementary Classification of Railway Systems Section, a high-level classification of railway systems and in Secondary Classification of Railway Systems Section a lower level classification. Finally, this article concludes, in Typical Rolling Stock Characteristics per Railway System Section, by summarizing typical rolling stock characteristics for each of the identified railway transport systems. Supporting figures depicting identified categories of individual railway vehicles, trainsets, and railway systems are included in the form of an Annex.

Individual Rail Vehicle Classification

Elementary Classification

At the highest level rail vehicles are distinguished based on their main function into powered and trailer vehicles (Fig. 1).

Power vehicles are self-propelled (i.e., they are equipped with traction motors). Such vehicles may:

- serve the sole purpose of hauling the trailer vehicles and are then called “locomotives” (or traction units, engines)
- transport a number of passengers and are then called either “single railcars” or “railbus” (when they have a driver’s cab at one or both ends) or “motor cars” (when they are remote controlled from another vehicle).
- be used for shunting hence they are called “shunting locomotives,” “shunters,” or “switchers”

Trailer vehicles are not self-propelled. They serve the purpose of transporting passengers or goods. Such vehicles may be classified into three (3) basic categories depending on their type of use (Metzler, 1981).

- Passenger vehicles (or passenger cars or coaches or carriages), which are intended to transport passengers.
- General—use freight vehicles (or freight cars or goods wagons or trucks), which are intended to transport goods.
- Specific—use freight wagons, which are intended for the transportation of certain types of freight only.

The term “rail vehicles” also encompasses the various engineering vehicles that are used to carry out track panel installation works as well as the various track inspection and maintenance works. These types of vehicles, due to their special function, may on their own be considered as a high-level special category (Fig. 1). These vehicles are further distinguished into two main categories, specifically into (Biasin et al., 2008):

- On track machines (OTMs), which include vehicles specifically designed for the construction and maintenance of the track. OTMs may be used in different modes, namely working mode and transport mode (either as a self-propelled vehicle or as a hauled vehicle).
- Infrastructure inspection vehicles or track recording or diagnostic cars, which are utilized to monitor the condition of the infrastructure. For such vehicles, there is no distinction between transport and working modes, instead they are operated in the same way as freight or passenger vehicles.

Secondary Classification

This section provides secondary level classifications of individual rail vehicles. Specifically, a secondary level classification is provided for power vehicles, trailer passenger vehicles, trailer freight vehicles, and engineering vehicles based on their technical and operational features.

Every rail vehicle, whether powered or trailer, consists of three basic parts as shown in Fig. 2. These are the car body or body shell, the bogies or trucks, and the wheelsets.

Figure 2 Main parts of a rail vehicle (Diesel locomotive). Source: Courtesy Siemens; Pyrgidis, C., 2016. *Railway Transportation Systems - Design, Construction, and Operation*. CRC Press, Boca Raton.

Several specific characteristics of these parts may be used to classify rail vehicles further. Specifically, the width of the axles may be used to classify rail vehicles based on the track gauge on which they may travel. Based on this criterion they may be classified into: (1) broad gauge vehicles, (2) standard gauge vehicles, (3) meter gauge vehicles, and (4) narrow gauge vehicles.

Moreover, the construction material of the car body may be used to classify modern rail vehicles into those possessing: (1) aluminum shells, (2) steel shells, or (3) stainless steel shells.

Power Vehicles

Locomotives depending on the type of traction power they utilize are classified into: (1) steam locomotives, (2) diesel locomotives, (3) electric locomotives, (4) hybrid locomotives, (5) gas turbine locomotives, and (6) fuel cell locomotives.

All these categories may be further classified based on a series of criteria specific to each category. For instance, steam locomotives may be distinguished based on the type of utilized steam (liquid/saturated or dry/superheated), their transmission method and whether the tender is part of or separated from the locomotive. Similarly, **Fig. 3** depicts a lower level classification of traction units based on power distribution. Diesel and electric locomotives are further classified based on the number of bogies and axles they have, as follows:

- BB (Locomotive with two twin-axle bogies)
- CC (Locomotive with two triple-axle bogies)
- CCC (Locomotive with three triple-axle bogies)

Electric locomotives are further classified based on (Frey, 2012; Sheed and Allen, n.d.; Railsystem, n.d.):

- The operating voltage/current under which they are designed to operate: AC locomotives, DC locomotives, multirole locomotives.
- The type of electric motor used: three-phase asynchronous motors, DC brush motors, synchronous AC motors.
- The solution used for power control and transmission between the electric motor and the bogies: mechanic, reostatic with series/parallel motor commuting and shunting, chopper, GTO/IGBT.

Figure 3 Classification of rail vehicles based on power distribution. Source: Modified from Ronanki, D., Singh, S., Williamson, S., 2017. Comprehensive topological overview of rolling stock architectures and recent trends in electric railway traction systems. *IEEE Trans. Transp. Electr.* 3(3), 724–738.

Hybrid powered vehicles utilize on-board rechargeable energy storage systems placed between the power-source and the transmission (Konarzewski et al., 2013). They may be classified based on:

- The nature of the power source, with the majority of hybrid vehicles utilizing an energy storage system in conjunction with Diesel, while other types of power source also exist (e.g., electric) (Hyatt, 2018).
- The type of storage system, for instance whether they use Ni-MH or Li-On batteries (Jeong et al. 2011).
- Whether the storage system is placed in series or in parallel.

Diesel locomotives can be further classified based on the solution adopted to transfer power from the prime engine (diesel generator) to the wheels. Thus, they are classified into:

- Diesel-mechanical locomotives, in which the power generated by the diesel engine is transferred to the wheels through a mechanical powertrain. This solution is usually adopted in vehicles with limited power (usually <300 kW).
- Diesel-hydraulic locomotives, in which the power generated by the diesel engine is transferred to the wheels through a torque converter. This solution is usually adopted in vehicles with power of middle-range (<1500 kW) and is very common in railcars.
- Diesel-electric locomotives, in which the power generated by the diesel engine is used to generate electric power, which is then transferred to electric motors in a way similar to that in electric locomotives. This solution is as of today the most widely adopted for mainline locomotives, and also the one that allows highest power, even exceeding 2000 kW.

Other types of power vehicles, such as railcars, may distinguished into types in a similar manner as presented for locomotives.

Trailer Passenger Vehicles

Classification of trailer passenger vehicles may be based on: (1) their internal arrangement, (2) the number of decks, (3) the maximum allowed running speed ($V_{\max}$), (4) the floor height, (5) the level of service provided, (6) their specific use, (7) the technology of equipped bogies/axles, and (8) the capability or not for tilting. Table 1 provides a list of the various types of trailer passenger vehicles based on each of the aforementioned classification criteria.

Trailer Freight Vehicles

General—use freight vehicles may be classified based on the type of covering and height of sides, into:

- covered wagons (or boxcars)
- open high sided wagons (or gondolas)
- open low sided wagons (or gondolas)
- open vehicles with no sides (or flat cars)

Specific—use freight wagons, may be classified based on the nature of products they transport into (indicatively):

- tank cars (for petroleum products, chemical or food products, for liquefied gas or cryogenic transport)
- refrigerated wagons
- hopper cars (with central, bilateral or pneumatic unloading)
- road vehicles carriers (double deck or single deck)
- cars for road/rail combined traffic (piggyback cars)
- cement wagons
- special flat cars for containers and other specific goods
- center partition cars

Table 1 Classification of trailer passenger vehicles based on various criteria

<i>Classification criteria</i>	<i>Trailer passenger vehicle type</i>
Internal arrangement	• Vehicles with compartments • Vehicles with individual passenger seats
Number of decks	• Single deck • Double deck
Maximum running speed	• Conventional speed vehicles ($V_{\max} < 200 \text{ km}\cdot\text{h}^{-1}$) • High speed vehicles ($V_{\max} \geq 200 \text{ km}\cdot\text{h}^{-1}$)
Floor height	• High floor • Floor at platform level • Combined solutions
Level of service	• Exclusively A Class vehicles • Exclusively B Class vehicles • A and B Class vehicles (C Class vehicles have typically been discontinued)
Specific use (indicatively)	• Passenger coach • Sleeping car • Dining car • Lounge car • Luggage car • Observation car • Specialized types (hospital car, driving trailer, dome car, private car, etc.)
Technology of equipped bogies/axles	• Vehicles with conventional bogies • Vehicles with Jakobs-type bogies • Vehicles with bogies with independently rotating wheels • Vehicles with self-steering axles • Vehicles with mixed behavior bogies (conventional and independently rotating wheels)
Tilting capability	• Active tilting vehicles • Passive tilting vehicles • Nontilting vehicles
Several criteria are applicable to powered vehicles as well	

Engineering Vehicles

As already stated in Elementary Classification Section, engineering vehicles are mainly distinguished into OTMs and infrastructure inspection vehicles. Within the first category, the following vehicle types may be identified based on the function they fulfil:

- tamping machines
- stabilizing machines
- grinding machines
- track renewal and track laying machines
- ballast regulating machines
- ballast cleaning machines
- drainage system cleaning machines
- formation rehabilitation machines
- catenary maintenance machines
- multifunction machines
- staff vehicles (facilities, offices, etc.)
- vehicles carrying cranes/lifts/telescopic ladders

While infrastructure inspection vehicles are initially distinguished into self-propelled, towed, or hi-rail vehicles, while further categorization is based on the measurement or imaging systems with which they are equipped. Based on said equipment, they may measure (ENSCO, 2015; Railway Technology, 2017) track geometry, rail profile and rail wear, equivalent conicity, third rail geometry, gauge restraint, ride quality, rail surface defects (corrugation), vertical axle box acceleration, tunnel clearance, ballast profile, track center distance, catenary parameters (voltage, pantograph pressure, wire position).

Table 2 Trailer passenger vehicles as classified by UIC

Type of vehicle	Code	Comment
Passenger coach with 1st class seating	A	
Passenger coach with 2nd class seating	B	
Composite coach with 1st and 2nd class seating	AB	
Coach with 1st class seating, kitchen and dining area	AR	
Coach with 2nd class seating, kitchen and dining area	BR	
Composite coach with 1st or 2nd class seating and a luggage compartment	AD, BD	
Luggage van	D	
Composite coach with 2nd class and a mail section	BPost	
Luggage van with a mail section	DPost	
Club car	SR	
Saloon coach	Salon	
Restaurant car	WR	
Sleeper	WL	(only in combination with A or B)
Narrow gauge coach	K	(only in combination with A, B or D)

Source: Adapted from Leo, n.d. *Types of coaches (in German)*. <https://web.archive.org/web/20081228112927/http://www.leo.org/information/freizeit/bahn/gattungszeichen.html>.

Classifications by International Union of Railways (UIC)

This section provides classifications for trailer vehicles (both passenger and freight) as proposed by UIC. **Table 2** provides a sample of their classification for trailer passenger vehicles, while **Table 3** does so for trailer freight vehicles. Individual rail vehicles need to be uniquely identifiable (Hamm, n.d.), but also need to be registered in a way that clearly communicates such information across various stakeholders. Therefore, codes and categorizations like the ones provided in this section are of use, when vehicles are marked and numbered according to national or international rules.

Definition and Classification of Trainsets

A “train” or “trainset” or “consist” is an operational formation consisting of one or more units, while a unit may in turn be composed of several vehicles. A trainset may be either of a fixed or predefined formation. A fixed formation is by definition not intended to be reconfigured, except within a workshop environment. It may be composed of only motorized or motorized and nonmotorized vehicles. A predefined formation consists of several vehicles coupled together, in a manner which is defined at the design stage, and can be reconfigured during operation (Biasin et al., 2008).

The combination of locomotives and trailer vehicles forms the loco—hailed passenger or freight trains. When two traction units are included in the same train formation then the operation is called “2-loco operation” (Pyrgidis, 2016).

The combination of single railcars, motor cars, and/or trailer vehicles forms railcars. The railcars can move in both directions without the need of a shunting locomotive in contrast with loco-hauled trains which need a shunting locomotive (Pyrgidis, 2016).

Push–pull trains are trainsets with a locomotive at the front (pull–push) or at the rear (push–pull), in which a trailer vehicle at the rear or at the front respectively is equipped with a driving cab (also called control car, driving trailer) allowing the train to be driven from either end. It may have a number of intermediate trailer vehicles, and can move in both directions without the need for a shunting vehicle. **Fig. 4** depicts both a push–pull and pull–push train formations.

The term “multiple unit (MU),” either electric (EMU) or diesel (DMU), refers to a trainset in which all units are capable of carrying a payload (passengers, luggage/mail, or freight) (Biasin et al., 2008). Specifically, they exhibit the following characteristics (Pyrgidis, 2016):

- Units are made of single railcars, motor cars and/or trailer vehicles semipermanently coupled.
- Driving cabs are provided at each end of the unit. The driver simply changes ends at terminus.
- Train length can be modified by adding or subtracting units.
- Power equipment is distributed along the whole train (only motor cars and single railcars have power equipment).

Assuming that PR refers to a single railcar, TC refers to a trailer vehicle and MC refers to a motorcar, example formations of multiple units would be: PR + TC + PR + PR + TC + PR, PR + MC + MC + PR, PR + PR + PR + PR.

Table 3 Freight trailer vehicles as classified by UIC

Type	Class	Description	Further classification
Ordinary open high-sided wagons	E	These have at least 85 cm high walls, side door and do not possess self-discharging equipment. They are mainly used for the transportation of coal, scrap, wood, or paper	• 2-axle vehicles • 4-axle vehicles
Special open high-sided wagons	F	These are mainly self-discharging hoppers, which use gravity based unloading. Typical such wagons are loaded with bulk goods, such as coal, ore, sand or gravel	• Hopper wagons • Saddle-bottomed wagons • Side-tipping wagons • Modalohr road trailer carriers
Ordinary covered wagons	G	These have a fixed roof and fixed rigid walls with sliding doors on each side. There are closable openings of various types along the upper third of the side walls. This class of wagons have been largely superseded by other classes and they are mainly used for the transportation of part-load goods or parcels	• 2-axle vehicles • 4-axle vehicles
Special covered wagons	H	These types of wagons are often distinguished by their large loading volumes	• Livestock wagons • Wagons with end doors • Leig-Einheit units • Ferry wagons • Sliding-wall wagons
Refrigerated vans or refrigerated wagons	I	Insulated covered vehicles, which are either cooled by a cooling medium such as water or dry ice like conventional refrigerated vans, or are machine-cooled wagons with their own cooling system	• 2-axle refrigerated vans • 4-axle refrigerated vans
Ordinary flat wagons with separated axles	K	Vehicles with no walls or low walls that are not higher than 60 cm	
Special flat wagons with separate axles	L		
Open multi-purpose wagons	O		
Ordinary flat wagons with bogies	R		
Special flat wagons with bogies	S		
Wagons with opening roof	T	This class of vehicles is mainly used for the transport of hygroscopic bulk commodities such as cement, plaster, lime, potash, and grain	• Lidded wagons with level floors • Sliding-roof wagons and sliding-roof/sliding-side wagons • Swing-roof and rolling roof wagons with level floors
Special wagons	U		• Bulk goods wagons for transporting powders, etc. • Dual coupling wagons for joining wagons with different coupling systems • Well wagons including Schnabel wagons • Self-discharging hoppers with loading hatches • Trials vehicles for RoadRailer and Kombirail systems for intermodal transport
Tank wagons	Z		• Tank cars to carry pressurized gases • Milk cars • Liquid hydrogen tanks • Pickle cars • Tank containers • Torpedo wagons or bottle cars • Vinegar cars • “Whale belly” cars

Railway Transport Systems Classification

Elementary Classification of Railway Systems

Railway systems are classified based on the geographic scope in which they operate as well as on their functionality / provided services. They are divided into: (a) Intercity systems, (b) Suburban systems, (c) Urban systems, (d) Steep gradient railway systems, and (e) Freight railway systems. These classes may be analyzed further as shown in Fig. 5.

Intercity railway systems serve trips greater than 150 km and usually link major urban centers. Assuming that $V_{\max}$ refers to the maximum running speed, V_c to the commercial speed, and L to the route length, then these type of systems include conventional speed railway systems ($V_{\max} < 200 \text{ km} \cdot \text{h}^{-1}$), high-speed railway systems ($200 \text{ km} \cdot \text{h}^{-1} \leq V_{\max} < 250 \text{ km} \cdot \text{h}^{-1}$, $V_c \geq 150 \text{ km} \cdot \text{h}^{-1}$, $L \geq 150 \text{ km}$) and very high speed railway systems ($V_{\max} \geq 250 \text{ km} \cdot \text{h}^{-1}$, $V_c \geq 200 \text{ km} \cdot \text{h}^{-1}$, $L > 150 \text{ km}$) (Pyrgidis, 2017).

The suburban railway is a means of transport usually running on electrified lines with characteristics adapted to commuter services within the impact limits of major urban areas (suburbs and satellite regional centers). Its range can exceed 100 km and may extend up to 150 km. The nomenclature varies. When covering lengths of 30–50 km it is designated as urban rail, while when it covers longer lengths it is sometimes dubbed as “regional” railway.

Urban railway systems include: (a) metros, (b) light metros, (c) tramways, (d) monorail systems, and (e) driverless railway systems of low/medium transport capacity.

“Steep gradient railway” systems serve small distance connections with a significant difference of altitude between the two edges of the railway line. They are separated into rack railways and cable propelled railway systems.

Freight railway systems may be either dedicated or share tracks with intercity or suburban railway systems. Freight routes have a range far longer than passenger routes, which may reach 10,000 km. Depending on their load per axle and the nature of goods transported they may be classified as follows:

- trains of conventional loads (axle load $Q \leq 25 \text{ t}$)
- trains of heavy loads (axle load $Q > 25 \text{ t}$)
- trains transporting hazardous goods
- trains transporting small parcels

Secondary Classification of Railway Systems

As already stated, metros may be classified into heavy or light, based on the passenger volume they serve. Moreover, metros being closed systems with generally uniform rolling stock are prime candidates for higher levels of automation. Therefore, they may be distinguished based on the level of automation they achieve from grade 1 (Automatic Train Protection with Driver) to Grade 4 (Unattended Train Operation) (UITP, n.d.). Moreover, metro trains may be distinguished based on the guidance systems they utilized namely into trains with steel wheel and trains with rubber-tyred wheels.

Tramway systems may be divided into four categories based on their technical/operational aspects, and more specifically on the nature and extent of services they provide. These categories are urban tramways, long distance tramways (tram-trains), tourist tramways or cultural heritage trams, and transport of freight.

Typically, tramway systems are also categorized based on the distance between the floor of the vehicle and the top of rail, into low floor (30–40 cm), very low floor ($< 30 \text{ cm}$), moderately high floor (40–70 cm), and high floor (70–100 cm). Moreover, depending on the percentage of their length which is low-floor, trams are distinguished in the following categories:

Figure 5 Classification of railway transportation systems. Source: Modified from Pyrgidis, C., 2016. *Railway Transportation Systems - Design, Construction, and Operation*. CRC Press, Boca Raton.

- totally (100%) low floor (low floor throughout the length of the vehicle)
- partially low floor (e.g., for 70% of the vehicle length)

Based on their power supply, they are distinguished into electrically powered via overhead wires, and electrically powered via supply at ground level. The latter may be conventional systems with a third rail, conventional systems with fourth and fifth rail, or possess more novel technologies such as reliance on inductive (contactless) transfer of energy to the vehicle. The electrical power supply may also be provided via energy storage devices, namely supercapacitors charged at stops via overhead wires). Finally mixed supply systems (e.g., overhead wires and storage devices) are also encountered.

Based on the formation of trains, trams may be divided into:

- simple
- articulated
- coupled (articulated or simple)

Cable propelled railway systems are divided based on the technique that is used for their acquisition of adequate traction for operating in steep gradients, namely into funicular (nondetachable cable), cable railway (detachable cable), and inclined elevator. Railway systems that utilize a rack/cog to achieve adequate traction for operating in steep gradients, are split into two categories based on the type of adhesion, namely into those with purely toothed (racked) tracks, and those exhibiting mixed adhesion operation (dual rack and adhesion systems).

Monorail systems are divided based on the placement of the trains in regards to the guidance beam and in regards to their transport capacity. Based on the former they are divided into straddled, suspended, and cantilevered systems. Based on the latter they are divided into small, large, and standard (compact) monorails (Kato et al., 2004).

In freight railway transportation, there are differences in the provided services which can be attributed to the variety of customer demands and, most importantly, to the volume and type of the transported cargo. The provided services fall into the following categories (Pyrgidis, 2016):

- less-than-wagonload services
- wagonload services
- services of combined transportation
- services of heavy haul transport
- special services

Less-than-wagonload services, also termed as part-load traffic, LCL (less-than-carload), or LTL (less-than-truckload) concern the transport of small packages under very strict time conditions and can be characterized as high speed freight services, e.g., TGV Postal high-speed trains and more recently the Mercitalia Fast service of the Italian State Railway (Troche, 2005; Zanuy, 2013).

Wagonload services are distinguished in Single WagonLoad (SWL) services and in TrainLoad (TL) services. SWL services involve cargo movements using single wagon trains. In such traditional freight services, the wagons (each wagon containing loads of single or multiple shipper(s)/consignee(s)) start their journey from different origin points or end their journey at different destinations, a fact which necessitates that they pass through intermediary marshaling yards. Regarding TrainLoad services cargo movement is performed by:

- Unit trains also termed full trains. These trains are formed of full wagons, which start from the same origin and travel to the same destination. These trains make full use of the tractive power of the locomotives. They do not stop at marshaling yards and they run between two specific terminal stations. They have one shipper, one consignee, one bill of lading and serve more than one final receivers (Zanuy, 2013).
- Block trains. These, like unit trains, run between two specific terminal stations without stopping at any marshaling yard. Their difference lies in the fact that they do not use all the power of their traction units while hauling.
- Exclusive trains. These are unit trains or block trains which serve a single final receiver.

Special services involve dedicated connections between mines and ports or mines and factories. The railway operates on a continuous basis ensuring a constant load flow, while special wagons are often used for transportation. A “door to door” delivery can also be considered as a special service, since the railway company undertakes receiving and delivering products from/to the user’s “door.”

In several cases (e.g., Block or Exclusive trains) the nomenclature varies. Block trains and exclusive trains are usually termed also unit trains

Typical Rolling Stock Characteristics per Railway System

This section provides in Table 4 typical rolling stock technical and operational characteristics for each of the aforementioned types of railway systems. These are indicative of the majority of railway systems currently in operation.

Summary and Conclusions

Railway vehicles may be classified based on various criteria and at different levels based on their integration in the wider railway system. Not all classification criteria are applicable for all types of vehicles and it is paramount to keep in mind the category of railway system in which the vehicles are called to operate, as this distinction shapes the vehicles characteristics to a great extent. Various organizations, from individual companies to international entities, use their own versions of existing classification and/or numbering systems, though guidelines exist from official sources.

Table 4 Typical rolling stock technical and operational characteristics per category of railway system

Railway system	Rolling stock characteristics			
	Traction type	Max running speed	Train formation	Other
High-speed railway	EMU or electric loco-hauled trains	$V_{\max} \geq 200 \text{ km} \cdot \text{h}^{-1}$	4–10 vehicles	- Conventional car body or car body equipped with tilting technology - Vehicles of normal or broad track gauge - Vehicles with Jakobs-type bogies or conventional bogies or bogies with independently rotating wheels - Single deck or double deck vehicles - Trains with air-tight car-body structure - Vehicles with compartments or with individual passenger seats - A and B Class vehicles
Conventional speed intercity railway	EMU or DMU or diesel or electric loco-hauled trains	$V_{\max} < 200 \text{ km} \cdot \text{h}^{-1}$	4–10 vehicles	- Conventional car body or car body equipped with tilting technology - Vehicles of all track gauges - Vehicles with conventional bogies (usually) - Single deck vehicles (usually) - Vehicles with compartments or with individual passenger seats - A and B Class vehicles
Suburban/urban/regional railway	EMU or DMU or diesel or electric loco-hauled trains	$V_{\max} \leq 160 \text{ km} \cdot \text{h}^{-1}$	2–8 vehicles/push–pull trains	- Conventional car body - Vehicles of all gauges - Vehicles with conventional bogies (usually) - Single or double deck vehicles - Vehicles with individual passenger seats (relatively high number of seats and low number of standing passengers)
Metro	EMU	$V_{\max}$: $90\text{--}120 \text{ km} \cdot \text{h}^{-1}$	4–10 vehicles	- Special rolling stock - Floor at platform level - Aluminum, steel, or stainless steel carbodies - Vehicles of normal or metric track gauge - Vehicles with conventional bogies - Vehicles with individual passenger seats (relatively low number of seats and high number of standing passengers)
Tramway	Electric traction (overhead wires, through the ground, with energy storage systems)	$V_{\max}$: $80\text{--}90 \text{ km} \cdot \text{h}^{-1}$	Articulated trains	- Special rolling stock - Aluminum carbodies - Vehicles of normal or metric track gauge - Low floor or very low floor vehicles - Vehicles with bogies with independently rotating wheels or bogies of mixed behavior - Vehicles with individual passenger seats (relatively low number of seats and high number of standing passengers)
Monorail	Electric motors setting a system of rubber tyred wheels to roll	$V_{\max}$: $60\text{--}100 \text{ km} \cdot \text{h}^{-1}$	Articulated trains (2–6 and rarely 8 vehicles)	- Special rolling stock - Suspended or straddle design - Rubber or metal wheels
Cog railway (pure rack)	Electric and diesel railcars	$V_{\max}$: $40 \text{ km} \cdot \text{h}^{-1}$	Usually a single railcar	- Special rolling stock - Vehicles of all track gauges (usually metric)
Funicular	Via pulled electric cables placed on the track superstructure	$V_{\max}$: $50 \text{ km} \cdot \text{h}^{-1}$ (usually $< 20 \text{ km} \cdot \text{h}^{-1}$)	Cabin vehicles (one ascending, one descending)	- Special rolling stock - Nondetachable vehicles—counter balance system - Vehicles of all gauges (usually metric)
Freight	Diesel or electric loco-hauled trains	$V_{\max} = 120 \text{ km} \cdot \text{h}^{-1}$	Very long trains (750 m–2 km for conventional loads and longer for heavy loads)	- Vehicles of all track gauges - Various types of wagons

Introduction

Maritime transport is a powerful and diversified industry with international dimensions. The international business environment in which maritime transport operates has changed significantly in recent years and makes it subject to a high degree of uncertainty (e.g., regulation). To understand this industry, the aim of this chapter is to introduce commonly used maritime shipping terminology (section, The Relationship Between International Maritime Trade and Maritime Transport), to discuss the market structure and setting that determines shipping companies' behavior (section, Market Concentration) and to look at another key issue affecting the shipping operator's performance, namely, the freight rate as an indicator (section, Supply, Demand, and Freight Rates).

The Relationship Between International Maritime Trade and Maritime Transport

International maritime trade is inextricably linked to maritime transport (i.e., concerns the movement of passengers and freight). The importance of international maritime trade for total international trade is considerable. The developments of each of them influence the other. It is a continuous interaction in which an economically sustainable response must be formulated to key trends such as industrialization and urbanization in emerging economies, changing demographics, disruptive technologies (a.o. digitalization, (semi-)autonomous ships, artificial intelligence), sustainability and climate-related disruptions, and trade and geopolitical tensions (Fig. 1).

If the trade forecasts of the International Monetary Fund (IMF), the World Trade Organization (WTO) and the World Bank come true, world total trade is expected to grow; and consequently world seaborne trade too. In what follows, world (seaborne) trade will first be considered before going deeper into the evolution of the world fleet.

In 2018, the world total trade (all modes) equalled 14.16 billion tons, of which 11.85 billion tons total seaborne trade. Since 2000, about 5.5 billion tons total seaborne trade was added. Seaborne trade expressed as a percentage of total trade corresponds to 83%, before the 1990s highly correlated to GDP; while put in global trade by value carried by sea, it amounts to about 70% (UNCTAD, 2019). To study world seaborne trade trends, figures for trade are often expressed in tons-miles or a ton of cargo moved one mile, a very accurate indicator of ship demand. Over the period 2000–09, total seaborne trade expressed in billion tons-miles

Figure 1 Relationship world total trade and maritime trade. Source: Own compilation based on Meersman (2009).

increased from 30,718 to 39,713. It is expected that in 2019 this indicator will exceed 60,000 tons-miles (2020: 62,000 tons-miles); thus nearly doubling due to more seaborne trade and increased number of long-haul trades (Clarkson Research Service, 2019; UNCTAD, 2019).

The choice was made to go back two decades, hence 1999–2019, so as to observe sufficiently long evolutions in the shipping business, which is marked by exceptional shorter-run spikes on the one hand, which have specific causes, and longer-run slowly evolving patterns on the other hand. Not only recapturing the past/present but also looking toward the future, it is particularly challenging for international organizations (International Monetary Fund, World Bank, International Transport Forum, UNCTAD), renowned industry analysts, classification societies, port authorities, and carriers to come up with accurate forecasts. A number of disruptive factors including economic (population, (de-)globalization, re-shoring), political (e.g., tariffs and trade tensions), climate, advanced technologies, infrastructure development, new regulations, digitalization and the growth of e-commerce are influencing the long-term outlook of the maritime sector. Forecasts (2030, 2050) cannot take away the growing uncertainty; at most isolate it. The uncertainty in the maritime transport environment can then be filtered by working with scenarios.

Commonly, three scenarios (low, base, and high scenario) are put forward; however given that the maritime sector faces a period of transformation, here, a min/max scenario is put forward. Numerical data below is based on the Shipping Review and Outlook tables published by Clarkson Research Service (2019). Based on different forecasts, the minimum scenario likely corresponds to an average growth of 0.5%–1% per annum, hence varying between 13.1 and 13.8 billions tons total sea trade; while the maximum scenario estimates a steady average annual growth rate of 2.4%–3.2% world sea trade volume (15.8 – 17.1 billions tons) over the period 2019–30. For the subsequent 2 decades, DNVGL (2018) assumes “a minimal 0.1% average world seaborne trade volume annual growth rate”; a very cautious view in comparison to other forecasts. Assuming 16 billions tons in 2030 and a growth rate of 1.5% per annum might result in 22.7 billion tons, just not doubling in comparison to 2019. In contrast, there is a greater consensus with regard to the expectations for the tons-miles indicator. Due to the fact that some maritime supply chains are expected to become more regionally oriented, the outlooks for the tons-miles indicator might level off as off 2030, given that the variable ‘distance’ (expressed in miles) may decrease.

Fig. 2 shows data about the world seaborne trade, with further classification by commodities, for 2000, 2009–19. First of all, all commodity categories are growing, but each has a different growth pattern. Next, the biggest shipping segments are liquid and dry bulk tonnage. Regarding the latter, commonly, a distinction is made between the major and minor bulk commodities. Under major bulk commodities is understood: iron ore, grain, coal, phosphates, and bauxite; while minor bulk commodities are agribulks, metals and minerals, and manufactures. Expressed in estimated billion tons-miles, the share of dry bulk amounted to 42.28% in 2000 and 49.55% in 2019. This evolution is due to the increase of the three most important raw material trades (iron ore, coal, and grain) and a considerable growth of the minor bulk during the last decade. In 2000, iron ore provides 38.43% of the volume for the dry bulk tonnage and nearly half of the volume in 2019 due to an increase of its related tons-mile. The share of liquid bulk decreased from 31% to 23% over the same period; while the share of containers increased from 9.49% toward 14.78%. In the category “gas,” LNG featured the biggest growth. Other dry cargo has no marked growth, rather only recovered from the economic crisis.

For the next 2 decades, it is expected that growth in the world seaborne trade will be driven by growth in containerized (however, at a lower space) and gas and chemical cargoes (i.e., other tanker trade); while the outlook for the raw materials of the steel industry (coal, iron ore) and the power generation (crude oil trade) are challenged by geopolitical tensions and the climate debate. The impact of this evolution on the maritime sector is still unclear. In total, maritime cargo might stabilize. However, given that the world population continues to expand, ensuring supply of food (grain) and energy will have to remain ensured and/or new supply chains (water, alternative energy products) may arise.

In addition to cargo, in 2018, passenger traffic accounts for 28.2 million passenger numbers, and a continued rise (e.g., Chinese tourist market) is expected (UNWTO, 2019). However, the magnitude of the growth rates might be suppressed due to the mega trends (more demanding customers, transforming passenger experience due to advanced technology like AI, growing public awareness of industry’s impact on the environment, overtourism, and so on).

Not surprisingly, the evolution of the seaborne trade is reflected in the development of the world fleet. Dry bulk cargo refers to cargo that is typically not carried in tankers. Following the supply structure proposed by Stopford (2009), Fig. 3 presents the classification of the world fleet over two decades.

Figure 2 World seaborne trade. Source: Own compilation based on *Clarkson Research Service (2019)*.

Figure 3 World total fleet. Source: Own compilation based on *Clarkson Research Service (2019)*.

The shipping market consists of two segments, tramping (no fixed sailing schedule) and (passengers, cargo) liners (fixed schedule). Homogeneous bulk cargoes are transported in conventional dry bulk carriers or tankers; while specialized or non-homogenous parcels (liquefied gas, chemicals, refrigerated, wood products, motorized vehicles) are transported each with their own fleet of especially designed ships (e.g., chemical parcel tanker, product tanker, reefer ship). Liner shipping relates to containership, Roll-on/Roll-off (RoRo), and other ship types.

In 1999, the world's total fleet (including offshore, dredgers, and other non-cargo) amounted to 61,770 ships, accounting for 776.6 million deadweight tons (DWT) of capacity. Deadweight tonnage or the cargo carrying capacity of a vessel, excluding the weight of the ship itself, is a way to measure the size of ships. In 2009, the world total fleet stood at 77,898 ships (1,206.5 million DWT). A decade later, the number of ships deployed corresponded to 98,027 (1,981.2 million DWT) or a growth factor of about 1.5 over the 1999–2019 period. In 2019, bulk carriers and oil tankers maintained the largest market shares of ships in the world fleet

Figure 4 CR4 for the tanker, bulk and container shipping market. *Source: Own calculations based on Alphaliner (various editions) and Clarkson Research Service (2019).*

(dwt), at 42.7% (1999: 35.9%, 2009: 35.4%) and 30.9% (1999: 38.0%, 2009: 34.8%), respectively. Within the segment “cargo liner,” the number of containerships doubled (1999: 2,539 ships, 2019: 5,295 ships); while the capacity increased by a factor 5 (1999: 62,3 million DWT (8%), 2009: 162,2 million DWT (13.4%), 2019: 265,9 million DWT (13.4%)). The majority of the containers are transported with fully cellular ships (expressed in 20 feet equivalent—TEU), accounting for 98% of the total container capacity. In 1999, the carrying capacity of the fully cellular ships stood at 4,260, 870 TEUs. A decade later, the container carrying fleet capacity amounted to 12,351,410 TEUs. In 2019, the world fleet of fully cellular containerships stood at 5,295 cellular ships for 22,324,652 TEUs.

As the unit of Fig. 3 is million dwt, the share of passenger fleet is very small (1999: 4.7 million DWT, 2019: 7.1 million DWT). Expressed in number of ships, this segment grew from 6,055 (1999) to 8,252 ships in 2019.

Gross tonnage (GT) is an alternative way to represent the size of the vessel (based on volume). In 2019, the total world fleet equalled 98,027 ships, including 41,984 non-cargo ships (21.5% offshore, 4.9% dredgers, 47.2% tugs, 1.0% cruise, 19.0% ferries and 6.1% other) or corresponds to 1,384 million GT, operated by 25,547 owners (4,071 tanker owners, 3,345 bulk owners and 923 container ship owners). Dividing the number of ships by the total of owners results in an average of 3.8 ships per owner; hence suggesting many small entrepreneurial shipping companies, particularly in the tramp business. Based on forecasts of Clarkson Research Service (2019), the world fleet is expected to increase to about 1,800 m GT (2.5% per annum) in 2030. From 2030 to 2050, the world fleet will continue to grow, but at a slower pace. There will be notable difference in growth pattern per ship type linked to growth prospects of the commodities (see above).

Having an idea about the demand (cargo side) and supply (ship side), the next section analyses the market structure more in-depth. Hereafter, the analysis is limited to the largest segments in shipping: bulk carriers, tankers and containerships. These are three different markets; Commonalities among them will allow identifying global trends.

Market Concentration

In order to better understand the behavior of shipping companies, insight in the market structure (i.e., ranging from perfect competition at one extreme to monopoly at the other) is needed. This section looks at two measures of market concentration, namely, the four-firm concentration ratio (CR4) and the Herfindahl-Hirshman Index (HHI) and the instability index to determine the magnitude of market share instability. The first measure computes the combined market share of the top four ship owners in the respective industries (Fig. 4 and Fig. 5). Summing the squared market shares of each owner in the respective industry and multiplying by 10,000 allows calculating the HHI. (Fig. 6) (Lipczynski and Wilson, 2017; Sys, 2010) The instability index is the sum of the absolute value of the change between two points in time in the market share of each firm (Hymer and Pashigian, 1962; Sys, 2009)

Fig. 4 shows the evolution of market concentration over the 1999–2019 period, on the basis of data from the AXS-Alphaliner top 100 (www.alphaliner.com) and Clarkson Research Service (2019). Clarkson Research Service publishes the top 50 tanker owners and top 50 bulk owners twice a year (spring and autumn); while Alphaliner publishes monthly the Top 100. Here, the CR4 is measured for the three selected shipping markets as the share of the four leading ship owners against the top 50. A high CR4 should be interpreted as a highly concentrated market. What conclusions can be derived from this?

Year	Tanker			Bulk carrier			Container liner shipping		
	1999	2009	2019	1999	2009	2019	1999	2009	2019
1	MOL	Frederiksen Group	China Merchant	COSCO	COSCO	COSCO	Maersk Line	APM-Maersk	APM-Maersk
2	VELA International	MOL	COSCO	MOL	NYK	NYK	Evergreen/Uniglor	MSC	MSC
3	Frederiksen Group	NYK	Euronav	NYK	MOL	K-Line	P&O Nedlloyd	CMA CGM	COSCO
4	NYK	Teekay Corporation	Bahri	P&O Group	K-Line	Starbulk carriers	Hanjin/DST-Senator	Evergreen Line	CMA CGM

Figure 5 Top four carriers. Source: Own calculations based on Alphaliner (various editions) and Clarkson Research Service (2019).

Figure 6 HHI. Source: Own calculations based on Alphaliner (various editions) and Clarkson Research Service (2019).

According to Lipczynski and Wilson (2017), any CR4 ratio of more than 40% corresponds to an oligopolistic market; thus all players recognize their interdependence. With respect to the container liner shipping, Fig. 4 shows that the CR4 has exceeded the 40% limit since the year 2007. In 2019, the top four container carriers nearly accounted for 60% of industry's carrying capacity. Moreover, the three consolidations waves are clearly observable: 1999/2000: Maersk Line + Sealand; 2005/2006: Maersk Sealand acquired RPONL; and the merger domino effect covering the 2015–18 period (2015: Hapag Lloyd + CSAV, Hamburg Süd + CCNI, CMA CGM + ODPR, 2016: COSCO + CSCL, CMA CGM + APL, 2017: Hapag Lloyd + UASC, Maersk Line + Hamburg Süd, 2018: COSCO + OOCL), resulting in increased concentration. On the other hand, both bulk-shipping markets are characterized by a less concentrated market. The top four carriers have a combined market share below 40%; the others are essentially fighting for the minor places. Clearly, the main characteristics of the tramp market are close to the perfect competition model ($CR4 < 5\%$). By economic theory, the perfect competition model is characterized by many buyers and sellers ("pricetaker"), perfect knowledge, identical products (homogeneous), free entry or exit, and firms that maximize profits. The last aspect is quite a challenge in the shipping industry.

In practice, there is no such thing as a maritime shipping market. Rather, it is a sum of different sub-markets, organized along the type of commodities/customers needs/ship types in bulk shipping, contributing to competition between the sub-markets; and the trade lane in the container liner shipping. The top three trade lanes, in terms of percentage of the global trade deployment by cellular TEU capacity, published by Alphaliner (2019), are Far East-Europe: 20%, Far East-North America (Transpacific) and 16%, Latin America related: 13%.

The comparison of the degree of concentration measure also clearly shows that the market structure is different. Both bulk segments are evolving toward perfect competition (i.e., less concentration, more competitive), while container shipping shows an increasing concentration trend.

Fig. 5 lists the four largest ship owners (capacity in service) compiled with data from AXS-Alphaliner and Clarkson Research Service. The restructuring of the COSCO group clearly results in a rise in its rankings in the tanker and container-shipping segment.

Fig. 6 shows the evolution of the HHI, an alternative measure of market concentration. The HHI can be as high as 10,000 (monopoly). The lower the HHI, the more competitive the market. The value of the HHI is meaningless, unless viewed against a benchmark: a value between 1,000 and 1,800 generally indicates moderate concentration, while any value over 1,800 points to a highly concentrated market (Shepherd, 1999; Sys, 2010).

Figure 7 Instability index. Source: Own calculations based on *Alphaliner* (various editions) and *Clarkson Research Service* (2019).

Given the earlier-mentioned guidelines, the bulk shipping industry must still be considered as unconcentrated. The HHI is never higher than the 1,000 limit. In general, a decrease in the HHI points toward a loss of market power and an increase in competition. Comparing with the container-shipping industry, in 2019, the HHI exceeded for the first time the 1,000 limit.

The fact that the tramp is operating in a more competitive market than container liner shipping is also clear from the instability index. This index is calculated with the Hymer-Pashigan or instability index. It is used to indicate the degree of competitiveness. The upper limit of the index is 1, corresponding with fierce competition; while the lower limit equals 0 or no variation in market shares (Fig. 7). Intensified competition among carriers corresponds with mergers and acquisitions (certainly in container liner shipping), the acquisition of Maersk's VLCC fleet by Euronav (ranked 14th in 2014, 6th in 2015) or the new division of tasks within the COSCO group (clearly visible for the bulk segment in 2016).

Actors in the tramp industry operating in a highly competitive environment will behave differently from ship owners/shipping lines in the container liner shipping industry, which faces less competition. From economic theory, companies in a competitive environment will keep their prices down and be as efficient as possible, simply to survive.

Knowing the market structure is important as it is central in strategic decision making and determines the carrier's behavior (profit, freight rate, etc.) (Baumol, 2004; Sys, 2010; Meersman et al., 2015; Lipczynski and Wilson, 2017).

In the next section, the focus is on the freight market, as fluctuations in freight rates (revenue) directly impacts cash flow, not to be underestimated in a particularly capital-intensive industry.

Supply, Demand, and Freight Rates

This section looks at the supply and demand dynamics. By the intersection of demand and supply, the freight rate is determined. Stopford (2009) defines the term freight rate as follows: "amount of money paid to a ship owner or shipping line for the carriage of each unit of cargo (tons, cubic meter, or container load) between named ports," hence covering the transport cost by sea. Chartering narrates to the chartering and operation of the ship.

Tramping

The demand for the most important commodity in the tanker trade (crude oil—left panel) and the bulk trade (iron ore—right panel) is placed against the supply of the shipping fleet. The year-on-year growth rates show a market that is often being affected by excess capacity. Maintaining some balance in the market in the demand-supply is more challenging in the dry bulk segment (Fig. 8).

Shipping indexes are the best way to evaluate how well the shipping market is doing. Different indexes are published in the maritime sector. The two main indexes, discussed hereafter below, are published by the Baltic Exchange and Clarkson Research Service. For the tanker sector, the BDTI/BCTI is the index of the applicable freight rate for the most important trade routes for crude (D or Dirty) and C or Clean (BCTI), which comprises the transport of refined petroleum products. For the dry bulk sector, the Baltic Dry Index (BDI)—a leading economic indicator of industrial production and economic activity, measures the supply and demand for bulk cargo, which is often just one kind of raw material per shipment (based on a weighted average of 11 different trade routes: grain 4, coal, 3, iron ore 3). The Clarksons Average Earnings reflects "a weighted average index of earnings for the main vessel types where the weighting is based on the number of vessels in each fleet sector" (Clarkson Research, 2019) (Fig. 9). Over the period

Figure 8 Supply and demand. Source: Own calculations based on *Clarkson Research Service (2019)*.

Figure 9 Baltic freight index and Clarksons Average Earnings. Source: Own calculations based on *Clarkson Research Service (2019)*.

1999–2019, the average value of the BFI (daily published) is 2,266 (with a standard deviation of 2,028 points). The Baltic Dry Index is more volatile compared to the indices commonly used for the tanker industry. In 2008, the BFI noted a historical record followed by a significant fall. Back to the new normal?

The variability of the freight rates for the tankers can be expressed in timecharter rates (US\$ per day) or in worldscale (W100–US\$ metric tons). The latter is used for voyage charter. The term “worldscale” refers to the cost of transporting a ton of cargo using the standard vessel on a round voyage (Stopford, 2009). A worldscale above 100 (spikes in 2000, 2004, and 2008) suggests a greater willingness to pay by the charterer, while a worldscale below 100 is rather the question of how much a ship owner is prepared to lose. Fig. 10 shows the evolution of the timecharters for different ship types (line), and the evolution of a voyage charter for VLCC (right panel), and iron ore (left panel)(column bar). In contrast to the VLCC and capesize, respectively, the freight rates and timecharter rates for the handysize, supramax, and panama fluctuate evenly.

Referring back to the megatrends (Fig. 1), geopolitical disruption might be the biggest concern for the capesize and VLCC.

Container Liner Shipping

In parallel to the tramp, here, Fig. 11 gives an overview of the supply-demand relationship (see left hand). Two observations impose themselves. Often supply is outpacing demand, resulting in a downward pressure on freight rates (see right hand) represented by the China/Shanghai Containerised Freight Index (CCFI/SCFI). Moreover, a steady increase in both the CCFI/SCFI and the timecharter rate index (Alpha liner) in 2009–10 can be observed; while the freight indices hold steady and timecharter rates increased in the 2016–18 period.

The findings of the earlier sections, in combination with economic theory, make clear that shipping companies active in the tramp market and therefore operating in a rather high competitive environment (see previous section) will behave quite differently than container shipping companies, who face a lower degree of competition. However, in practice, shipping companies facing competition from many other carriers will have a hard time raising their prices, hence, they need to operate as efficiently as possible, if they are to survive in this sector. To cope with economic, political, technological, environmental disruptions, carriers focus on further cost reduction via innovation.

Acknowledgment

The authors want to pay their respects to Prof. Dr. Eddy Van de Voorde and Mr. Honoré Paelinck for their continuous encouragement to study the maritime sector more and more in-depth. Next to this, the authors want to thank Ruben Van Deuren for his support with making the available data congruent.

Biographies

Associate Professor, Christa Sys currently is holder of the BNP Paribas Fortis chair on transport, logistics, and ports at the Department of Transport and Regional Economics. Until October 2013, she was scientific director of the Research Centre on Freight and passengers flows. Next, she is course coordinator for the courses “Business Environment,” “Maritime Economics and Businesses” and “Maritime Supply Chain” at the Centre for Maritime and Air Transport (C-MAT). She also teaches at the Faculty of Business and Economics, University of Antwerp. Her educational activities focus on (operational aspects of) maritime transport, maritime supply chain, transport economics and inland transportation. Her research centers on maritime economics and co-operation and competition in shipping. She jointly graduated as a doctor in Applied Economics at the Ghent University and the University of Antwerp (December 2010). Her doctoral research dealt with the competitive conditions, the concentration and the market structure of the container liner shipping industry (link). This research was awarded by the Section of Technical Sciences of the Royal Academy for Overseas Sciences with the General Manager Fernand Suykens Prize for Port Studies.

Thierry Vanelslander currently is Associate Professor at the Department of Transport and Regional Economics. He graduated as a doctor in Applied Economics at the University of Antwerp. Until 2013, he was holder of the BNP Paribas Fortis chair on transport, logistics, and ports. Until halfway 2009, he was director of the Research Centre on Freight and Passenger Transport, hosted by the Department of Transport and Regional Economics. He is currently course coordinator for the courses “Management of Innovation and Technology” and “Port Economics and Business” at C-MAT, and “Transport Economics” at the Faculty of Applied Economics. His research focuses on business economics in the port and maritime sector, and in land transport and urban logistics. His PhD dealt with co-operation and competition in seaport container handling. He is also the chair of the World Conference on Transport Research (WCTR) Special Interest Group A2 (Ports and Maritime), and topic area manager for WCTR’s track A (Transport Modes). Equally, he is the chair of the Freight & Logistics group within the European Transport Conference.

Introduction

Dealing with the geography of maritime transport has two directions of which only one can be chosen in this article: (1) doing a geography of maritime transport or (2) analyzing the geography of maritime transport itself. Far from proposing an exhaustive review and comprehensive history like in a bibliometric study, we propose in this article to ask one central question: what makes maritime geography different from—or linked with—maritime/transport studies and geography/spatial sciences in general? Although such a question seems to point to a very specialized research arena, it has a wide range of possible answers. We thus selected two major issues that concern many other (if not all) arenas: (1) data visualization and spatial shift as well as (2) network science and complex systems. Such an angle of attack has two merits.

First, it avoids repeating the usual contents of maritime textbooks and official reports, where the evolution of technology, cost, and traffic is already well covered, and of dedicated geography handbooks showing major shipping routes, the ranking of world's top ports, and other features such as traffic distribution by fleet, continent, flag, etc. The majority of maritime geography long remained a descriptive collection of information constantly updated but with no ambition to connect other domains. Despite its pioneering role in mapping world shipping routes based on real data, maritime geography soon became closer to maritime economics and management with a growing emphasis on actors and their strategies, cf. the behavioral turn. But the spatial turn converged with a growing interest for the sea from other disciplines, so that numerous visualizations of maritime transport emerged in the past decade or so. In recent years, several international and/or nongovernmental organizations produced huge reports about maritime transport using cartography, such as the United Nations mapping piracy acts since the mid-1990s (UNITAR) and calculating a Liner Shipping Connectivity Index (UNCTAD), the OECD measuring the competitiveness and visualizing the maritime forelands of global port cities, the World Bank displaying the connectivity, efficiency, and economic development of Mediterranean maritime networks, and the European Commission Joint Research Center analyzing vessel position data for practical purposes and calculating a composite index of global urban accessibility including vessel flows (see a recent review in [Ducruet, 2017](#)). After presenting a critical review of existing visualizations of maritime transport, we propose a new methodology based on the new software Geoseastems.

Second, it is interesting to compare how maritime geography had been adopting dedicated analytical tools such as network analysis, from the early times up to nowadays. Is maritime transport a specific network? What is the influence of its spatial nature on its structure, morphology, and topology? In this approach, the network concept will be extended to other dimensions such as firms networks in the maritime sector as well. This approach thus places the geography of maritime transport, should it be performed by geographers or not, at the center of multiple arenas such as corporate studies, urban studies, network studies. To reach such an objective, recurrent topics such as port–city relationships, technological evolutions, traffic distribution, hinterland connectivity, port governance and supply chain integration will be inevitably dealt with, to name but a few. Case studies as well as general models are selected to further illustrate what is the geography of maritime transport.

Mapping Maritime Transport

The Evolution of Classic Maritime Cartography

It is a fact that only a dozen maps of world shipping flows have been produced until the years 2000s (Ducruet, 2015). Historically, maritime maps serve overseas explorations and are strongly impregnated by human imagination on sea monsters and mysterious places. In the 19th and early 20th centuries, such maps gained in precision, indicating major and minor sea lanes, and sometimes the services of specific carriers, notwithstanding information on natural conditions. The emergence of flowmaps only occurred in the 1940s from French and US geographers representing global maritime flows based on historical archives and customs data, employing, at the time, state-of-art technique of flow visualization.

In the mid-1970s, US authorities provided a more systematic cartography of shipping flow density based on a world square grid. But filling cells with the number of vessel trips was not the most efficiency method compared with nowadays tools. Another exception is a PhD thesis from Le Havre University mapping the main interport container flows in the early 1990s. All other maps before the 2000s remained broadly estimated drawings of major maritime routes, published in related textbooks, but not based on actual data. Exceptions are traffic maps showing maritime trade volume per continent and region but not between them. Old data such as ship logs were used to produce similar maps but with a very different purpose: the reconstitution of past weather conditions across the globe (the CLIWOC project). Text-based sources and archeological records helped to reconstitute Roman and Greek routes of the Antiquity, while local port registers allowed to map 18th century French trading routes (the Navigocorpus project), Venetian trade (1283–1453), slave voyages from Africa to the Americas (1514–1868), and an animation of British Royal Navy ship movements (1913–1925) using CartoDB. Other known sources on past maritime transport remain to be systematically exploited, such as the Suez Canal archives (1865–today), the Sound Toll Registers (1497–1857), and the Dutch East Indian Trading Corporation with 25 million ship records (1595–1795).

The discovery of Lloyd's List publications on global and daily vessel movements, covering approximately 80% of the world fleet and published since 1880 (1696 for the British fleet only) opened the path to plenty of previously unthinkable analyses, long-term and at the global scale. For instance, mapping the global maritime network at the continent level between 1890 and 2010 clearly confirmed the shift from Atlantic to Pacific, with the drawback of using vessel calls instead of vessel tonnage in recent years as ships grew in size and rationalized their services (Fig. 1).

About maritime transport as a firm or alliance, mainly French and Canadian geographers offered, from the mid-2000s onwards, maps of individual ocean carriers. Such a shift to more managerial aspects was motivated by the growing bargaining power of large companies over the entire supply chain including port and terminal operations as well as logistics. Data were usually obtained directly from websites or from yearbooks such as Containerization International, detailed at a given point in time the scheduled services of each company. One of the first maps of the kind showed the service geography of Evergreen and COSCON in 1990 and 2000 with the main ports of call. Another study compared the global network of the largest shipping lines in 2002 based on no less than 601 services and 440 ports, but the maps were aggregated by continent. This helped to categorize firms and better understand their mainstream or niche strategies according to their geographic coverage and their nationality. Later on, parent studies followed, such about COSCON in 1990 and 2000, mapping its services related with China, to discuss competition and integration trends, and about the historical development of CMA-CGM and Maersk, questioning the respective roles of public and private forces conducting to routing choices, with a growing emphasis on market power and efficiency.

Finally, some types of studies looked at vertical integration, cooperation, and interfirm agreements while others looked at maritime firms through the localization of their headquarters and establishments, the local determinants of maritime advanced producer services (APS; e.g., finance, brokerage, insurance), should it be globally or at the intracity level, also questioning their colocation with other APS or with commodity traders as well as their concentration in global cities. The modal specialization of cities was measured in Europe based on the portfolio of about 8000 transport companies (Kompass database), discussing the varying importance of vertical integration and the strong national influence. Such studies looked more at the sectoral disaggregation rather than individual companies.

Other disaggregated works relevant to the geography of maritime transport also include the analysis of ship-to-ship interactions, should it be for military purposes (cf. tactical and telecommunication networks) or understanding a particular type of transfer of goods, people, or information as specific points in the sea, considering the ship “as a vehicle for knowing and understanding colonialism, commerce, trade and conflict; embodied and resistant performances, and residual materiality, demonstrating the place of the ship in geography”. Certain geographers got even closer when interviewing captains and mariners to map their mental representation of the ocean, having in common with the former that maritime issues are peripheral in geography.

The Digital Era

Tremendous progress has been made since the early 2000s in the visualization of maritime transport. Numerous online tools serving the calculation of interport shipping distances, (e.g., Sea-distances, Searates), replacing the tedious port-to-port printed matrices. Other tools were designed to measuring intermodal shipping costs as well as the environmental, energy, and economic impact of freight transportation (e.g., GIFT model). Radar and satellite data had been the common material to be used for a wide variety of analyses and visualizations about ship emissions, environmental impacts of shipping, accidentology, navigability, security, vessel trajectories, and coastal management. The latter works remained somewhat separated from the ones presented in the previous

Figure 1 World distribution of vessels calls in 1890 and 2010.

section (social sciences), being more on the side of traffic engineering and operations research. Yet, this digital data could not go back prior the mid-2000s, but gained in popularity with the emergence of numerous online resources of which the now famous marinetraffic.com providing the real time position of vessels, freely accessible.

Numerous maps using such real-time data were thus proposed, for the sake of obtaining a more precise vision of corridors by type of ship for instance (cf. cargo and tanker ships by ShipMix), a multilayered cartography of the Anthropocene (Globoïa), global heatmaps of ship densities (Marinetraffic and ExactEarth). Dynamic visualizations have also been proposed by FleetMon Satellite AIS and FleetMon Explorer, of which the Shipmap project looking at environmental impacts. Other explored issues include the analysis of ships' traces across oceans using Advanced Very High Resolution Radiometer (AVHRR) data from space, noise data from waves and currents of which anthropogenic (e.g., <https://www.oceannoise.com>) using for instance NOAA AIS data. The rise of online mapping solutions also includes the European Atlas of the Seas (European Commission), route-planning algorithms to model maritime paths, the upcoming Google Oceans application, and the OpenSeaMap project with complementary information on shipping lanes.

Despite the mentioned advances, there was little if no possibility to map past maritime flows and thus to understand the long-term evolution of maritime transport. Fig. 2 provides a recent example based on 2008 data of a flowmap and heatmap based on the same information. Each map shows a different dimension; the heatmap is somewhat biased by extreme values (port traffic) in East Asia while the flowmap is more precise in terms of global coverage and the distribution of routes, with lesser concentration. Such visualizations were made possible using a virtual maritime grid based on distance and cost of supporting links, after the world map had been divided into squares through eight iterations and their centroids linked with the impossibility to cross land surfaces.

Maritime Transport as a (Spatial) Network

The application of graph theory to maritime transport started in 1968, in a Canadian PhD thesis about Vancouver (Robinson, 1968), but had only a handful of followers until the late 1990s and early 2000s in isolated theses and articles not even mentioning each other. A rapid count using Google Scholar revealed two facts: the very low number of works mentioning explicitly “maritime network” in French and English languages (i.e., less than 1% of all transport network studies) and the majority of such works using the concept of network in its common sense but without engaging in graph theory and the emerging network science. The main value of applying graph theory to maritime transport had been to provide local or global centrality and connectivity indicators, thereby creating more links with other modes and domains as well as complementing the usual description of tonnage. In this section, we discuss the merits and demerits of such a conceptual and methodological adoption through two main themes: regionalization and globalization; cities and regional development.

From Regional to Global Maritime Networks

The Maritime Region as a Framework

Choosing a specific part of the world to study connections between ports made the study of maritime transport more geographic. Several studies of the kind emerged in the mid-2000s, about arbitrarily defined regions. This led to the questioning of comparability across regions and of the concept of “maritime region,” often badly defined and corresponding to various realities such as facade, range, seaboard, basin, port system (Lewis and Wigen, 1999). The regional scale is also a way to discuss wider issues of which regional integration, transnational and cross-border studies, and the importance of proximity in the pattern of flows. Yet, such

studies oscillate between understanding the network (actors), the region (territories), or both. A study of port geography papers (Ng et al., 2014) concluded that among them, 48% focus on one single port, 32% on a single country, 14% on a transnational area, and 6% on the world. The national scale has been relevant for countries made of numerous islands, as seen with analyses of the Finnish, Indonesian, and Greek maritime networks, mainly from a passenger and regional planning perspective.

Transnational studies mainly focused on container shipping, with many works on the Caribbean and Mediterranean basins, due to their situation as crossroads and the proximity to Panama and Suez canals, respectively. Network analysis was useful to compare the connectivity of intra- and extra-regional linkages, the role of main shipping lines versus alliances, and the emergence of hub ports. More recent studies explicitly questioned the integration level of specific systems, such as the North European port range from Le Havre to Hamburg, southern Africa, the Canary Islands, the East-West circumterrestrial corridor, and increasingly, the “new” Maritime Silk Road deployed by China through its vision “One Belt, One Road” (OBOR). Comparative studies also emerged, also including North Europe and East Asia, but mainly for the sake of further understanding transport actors, with little citations about regional studies.

1996

Figure 4 Nodal regions in the global container shipping network in 1996 and 2006.

2006

Figure 4 (Continued)

The main outcome had been to observe variations in the level of regional network centralization around hubs, from homogeneous to polarized or polycentric maritime regions; some of them being more or less under the influence of alliances, hubs, and related dynamics such as the rationalization of services. Another result was that the multiplication of nodes and links could mean both regional integration and transshipment hub centralization, depending on the context. Nevertheless, such regional studies often faced the difficulty of disentangling flows of various scale (e.g., short-sea shipping, trunk lines, and feeder) as well as territorial vs supply chain effects.

Another outcome had been to reveal the influence of political borders and other “barrier effects” on the changing distribution of regional maritime networks. First came a series of works on North Korea, revealing its shrinking maritime foreland due to internal and external crisis following the end of the USSR and socialist block; the multiplication of inter-Korean shipping linkages following the 2000 presidential summit and the 2004 maritime agreement, and even the concentration of most North Korea’s traffic between the main ports of the respective capital cities, Nampo and Incheon, before North Korea’s connections became, in the late 2000s,

Figure 5 Graph visualization of canal and port centrality in 1996 and 2006.

dominantly Chinese (Fig. 3). Similar maps were proposed to study the interplay between border effects and shipping patterns in Maghreb, Northwest Africa, South Asia, and the Soviet Union, at times of crisis and independence, showing important shifts overtime. In central Maghreb, ports of the three countries (i.e., Morocco, Algeria, and Tunisia) remained disconnected in the mid-1990s. Ten years later, Algiers somewhat increased its dominance, albeit mainly domestic, until the opening of the new hub Tangier-Med (2008) attracted all the regions' main flows for transshipment, competing with the other external hubs of Algeiras and Marsaxlokk. At the contrary, the analysis of the Northeast Asian liner shipping network since the mid-1990s questioned the rise of Shanghai as Asia's new hub. The application of single linkage analysis demonstrated that South Korea, and in particular Busan port, remained dominant in the region despite rapid Chinese port growth and surpassing Hong Kong, due to its logistics hub strategy and the fact that China is still hampered by customs procedures and other political factors that stand in contrast with its enormous potential.

Substructures in the Global Maritime Network

The search for substructures (also coined communities, clusters, or subgraphs) is one major pillar that had been applied successfully to maritime transport. Numerous algorithms dissect the network into groups of nodes, this time without an arbitrary definition of the "region," but still trying to delineate meaningful elements, where geography, politics, and economics also create barrier effects. Physicists were the first to apply modularity to the global networks of tankers and container ships, confirming a strong influence of spatial proximity on the delineation of clusters, their initial goal being to further understand marine bioinvasions. Chinese geographers were the first to reveal the world's container hubs and their respective "regions" where they dominate; they had many followers. Single linkage analysis applied to the global container shipping network in 1996 and 2006 (Fig. 4) confirmed the importance of geographic proximity as most subnetworks were in fact ports in proximity of one local hub. However, one exception to this was the giant "nodal region" centered upon Hong Kong, extending towards both North America and Europe, and including the whole African continent in 2006, mainly driven by the "China effect." Another way to see such changes was to map the entire network and the centrality of port nodes (Fig. 5). The major change observed was the growing centrality of Asian ports and the growing bypass of the interoceanic canals to connect Asia with Africa and Latin America more directly, with increasing transversal linkages between the world's two main poles, Asia-Pacific and Euromed-Atlantic.

With the prime goal to check the multiplex (or multilayered) structure of the global shipping network, the application of single linkage analysis to five layers of maritime flows (containers, passengers and vehicles, solid bulks, liquid bulks, and general cargo) confirmed that not only more diversified ports are larger and more central more faraway connected than more specialized ports, final results also concluded that shorter linkages are more diversified; mostly container ports dominate their respective nodal region, and the latter regions tend to specialize in one main traffic type (Fig. 6). Such invariants largely confirmed stylized facts found in urban studies for instance. Other clustering algorithms helped revealing the other side of the coin: the permanency of "weak links", outside main hubs, for cultural and historical reasons. The Bisecting K-means algorithm applied to the Atlantic network revealed tight but invisible links between the Iberian Peninsula ports and Latin American ports, while the topological decomposition algorithm demonstrated that in the worldwide network, the intercontinental linkages between small and medium-sized ports always

contained one or more European ports in addition a port of the former colonial world, showing the traces of past empires. These nonhierarchical subnetworks carry a lot of questions about the volatility of the supposedly economically driven containerization. Links could be made with key notions of resilience, robustness, and proximity in geography and other disciplines.

The long-term analysis of the global maritime network (1890–2010) confirmed the shift from a polycentric and dense structure (colonial times) to a bipolar and centralized structure (post-1950s), together with a growing simplification or rationalization of the network (Fig. 7). One of the main conclusions was that this centralization upon fewer large hubs overtime had not been caused, but reinforced by, containerization, which is often seen as the turning point in shipping pattern distribution, although similar competition fostered by technological evolution also occurred in the past such as from sail to steam and combustion, long before the current era of mega-ships. The most striking is that the basic material used for such studies had never been used before, although it had been cited two or three times in the works of . . . geographers! The *Lloyd's Shipping Index* allowed to build a global interport matrix comprising nearly 9000 ports, 200,000 linkages, and 850,000 vessel movements. The main conclusion was that the global maritime network shifted from efficiency/robustness to centralization/vulnerability.

Figure 6 Network diversity and centralization of global maritime flows in 2004

Figure 6 (Continued)

Socio-Economic and Territorial Determinants

The “location” of ports is often given little importance in maritime network studies, as their vast majority only considers the topological space, and the plethora of works about port-city relationships is often theoretical, monographic, without a relational perspective. This section investigates the interplay between maritime transport and two main components of geographic space: (1) cities and (subnational) regions and (2) other transport networks of which the road network principally.

Cities, Regions, and Maritime Flows

Cities and regions have been the focus of many works on commodity chains, production networks, innovation clusters, and so on (Hall and Hesse, 2012), but mostly from the perspective of multinational firms’ networks, airlines, etc. Never have cities been confronted in a systematical manner to maritime flows on a global scale and in the long-term. More likely are models and case studies of port-city separation and waterfront redevelopment, transforming former port areas for new urban uses. A minority of works still demonstrate the positive (economic) impact of ports on their belonged territory, especially in emerging economies (cf. BRICS countries), but most scholars ignore the city or see it as a constraint to port development which should be bypassed due to

lack of space and congestion. In addition, new ports and transit hubs have barely any effect on their outlying environment. Port-related benefits (value, employment) tend to concentrate in locations without necessarily having a port, like inland or coastal nonport cities.

However, the emergence of large-scale quantitative analyses of port cities and regions in the 2000s allowed detecting important linkages, such as the fact that in Europe, North America, and Japan, larger, richer, denser, and service-oriented cities concentrate the most diversified and valued flows whereas regions handling bulks remain often specialized in the primary sector. Such findings motivated a relational study although most of the time, transport and communication networks were studied without proper urban or regional attributes. The first-ever analysis of the world's cities connected by water, based on theories of urban systems, was fruitful in many ways. Mains results (1890–2010) confirmed that the immense majority of world maritime traffic kept concentrating in larger cities, while the latter always exhibited, on average, superior centralities of all kinds, higher rich-club coefficient, higher commodity and ship type diversity, and farther connectivity than smaller cities. Interestingly, the fading linear correlation between urban population and vessel calls observed at port cities per se had, at the contrary, constantly increased at extended urban regions, i. e., cities hosting or not ports but being near the coast, thereby confirming the dilution of hinterlands and the changing meaning and nature of the study unit. This study also confirmed that current global cities like London, New York, and Tokyo had been the world's largest maritime hubs in the 1950s, but lost their dominance to more efficient hubs in the following decades (Fig. 8), such as Rotterdam and Singapore, which are large cities but not the largest.

The Interconnection with Other Networks

Although the idea of studying how different (transport) networks combine dates back to the 1960s in geography, it is only very recently that such a task had been achieved. A growing number of theories and empirical studies of so-called coupled or multiplex networks emerged in natural and social sciences in the late 2000s. Transport studies have increasingly seen maritime transport as one segment only of a wider supply chain comprising other modes, while land transport as a whole often represents about 60% of the

Figure 7 Density evolution of the global maritime network, all vessels (A) and containerships (B).

total cost of moving a container from origin to destination. Physicists and geographers first analyzed the coupling or “intersimilarity” between global airline and maritime networks. The online GIS ORBIS allows calculating the time and cost of travelling through the sea-land network in Roman antiquity. All other studies of the kind did not include the maritime mode, such as airline/Internet, airline/multinational firms, and airline/road/rail to name but a few.

We present in more detail recent efforts to push further the analysis of sea-road networks. One major obstacle being the absence of data on road (freight) flows, except from certain customs data or commodity flow surveys in developed countries. Such an approach having a global ambition, it relies on maritime flows on the one side and road infrastructure on the other. Raw data from OpenStreetMap was modelled and thus simplified taking into account the quality, rank, and speed limits of street segments to construct a global road network connecting both ports, port cities, and nonport cities inland and along coastlines. Applications were made on Australia and Europe (Fig. 9). In both cases, it revealed that combined land-sea centrality is always more correlated with urban population than single centrality.

Figure 8 Urban centralization of the global maritime network in 1950 and 2010.

Figure 9 Sea-land connectivity of European ports and cities in 2008.

of space is increasingly taken into account after a period more focused on actors and strategies, the two being not mutually exclusive. Maritime transport has its specificities in terms of industry but it clearly remains, today, a useful way to understand the world from the local to the global.

Introduction

No other mode of transport is as important for international trade than maritime transport. According to [UNCTAD \(2019\)](#), maritime transport carries around 80% of total trade. The strong growth of the global economy, at least after the end of WWII, can be significantly attributed to, and linked with, a similarly strong growth in international trade, which in turn would be impossible without important and ground breaking advances in ship design and propulsion, cargo handling equipment, ports and terminals technologies, and intermodal supply chains, among other factors. Such advances were caused, at least in part, by the ever-lasting drive of the shipping industry to innovate and offer services of competitive cost and quality to shippers.

Maritime transport is very diverse, spanning a very broad variety of different ship types and several segments of shipping markets and services, ranging from tankers to containerships, from passenger to cargo services, from deep sea to short sea routes, and from bulk commodities to unitized cargoes. All this diversity has evolved over a long history that has paralleled the evolution of human civilization, and the ever-lasting drive to explore new worlds, engage in trade, connect remote regions and peoples together, and even wage wars among nations. To state an example, the port of Piraeus container terminal, operated by Cosco Pacific and which moved some 5,650,000 TEUs in 2019, is in exactly the same stretch of water where, some 2500 years ago, the fleet of Themistocles demolished the fleet of Xerxes in the naval battle of Salamis.

Clearly there is as much resemblance between ancient times and today as between an Athenian trireme and a 20,000+ TEU containership. So, making a long-term prediction what maritime transport will look like in thousands or even hundreds of years from now is impossible. A more reasonable question is, can we at least predict what it will look like in the next 30 to 50 years? It turns out that the answer is just as difficult. The purpose of this chapter is to attempt to present an exposition of some of the main factors that come into play as regards the future of shipping, by focusing on a 30–50 year time horizon. It is of course realized that the exposition for such an important topic is to a large degree subjective and incomplete, especially also given the size limitations of this chapter.

There is no doubt that autonomous shipping and digitalization are technological mega-trends that may radically transform maritime transport in the years to come. Autonomous shipping in particular has the potential to radically transform the face of shipping in the future. However, and in spite of much progress, there remain many issues mainly as regards maintenance, resilience, and legal and insurance matters, before autonomous shipping can become the norm. In this chapter, we shall leave these specific trends aside and focus on the *drive to decarbonize shipping*, which is a goal that is very pressing and very much connected to the global quest to combat climate change. So, in the rest of this chapter, we shall discuss the drive to decarbonize shipping and then we conclude with some thoughts on what may lie ahead.

The Drive to Decarbonize Shipping

General

Perhaps no other regulatory development in the history of maritime transport is likely to have a higher impact on its future than the decision of the 72nd session of the Marine Environment Protection Committee (MEPC 72) of the International Maritime Organization (IMO) in April 2018 to achieve by 2050 a reduction of at least 50% in green house gas (GHG) emissions from international shipping, vis-à-vis 2008 levels. There is also an intermediate target to achieve by 2030 at least a 40% reduction of CO₂ emissions per transport work, against vis-à-vis 2008 levels. The so called Initial IMO Strategy ([IMO, 2018](#)) is in the form of Resolution MEPC.304(72), and includes, among others, the following elements: (1) the vision, (2) the levels of ambition, (3) the guiding principles, (4) a list of short-term, medium-term and long-term candidate measures with a timeline, and (5) miscellaneous other elements, such as follow up actions and others.

The so-called 3rd IMO GHG study (Smith et al., 2014) provided updated estimates of CO₂ emissions from international shipping from 2007 to 2012. The 2012 figure, estimated by a “bottom up” method, was 796 million tons, down from 885 million tons in 2007, or 2.2% of global CO₂ emissions. It should be noted that the equivalent percentage reported in the 2nd IMO GHG study (Buhaug et al., 2009) was 2.7% for 2007 fleet data. CO₂ from all shipping was estimated at 940 million tons in 2012, down from 1100 tons in 2007. The reduction from 2007 to 2012 was mainly attributed to slow steaming due to depressed market conditions after 2008. The 4th IMO GHG study, going to 2018 fleet data, is expected to be released in late 2020.

As expected, much of the discussion after the adoption of the strategy in 2018 has focused on short-term measures, and specifically on how such measures can help achieve the intermediate 2030 target, reduce CO₂ emissions per transport work, also known as “carbon intensity,” as an average across international shipping, by at least 40% by 2030, compared to 2008. As this chapter was being finalized, no IMO decisions on such measures had been made. Whatever these measures might be, none of them are expected to change the picture of maritime transport in any significant sense. However, if one stands any reasonable chance to reach the 2050 GHG reduction target, it is clear that some drastic changes should be expected. Among such changes, the use of alternative (low-carbon and zero-carbon) fuels seems the most important instrument.

In fact, it is very clear from the Initial IMO Strategy that such alternative fuels are centrally placed within the IMO decision document, and reference to such fuels is made in many instances in that document. If anything, this reflects the fact that the development and eventual use of such fuels is a matter of high priority for the maritime industry, particularly if the targets set in the IMO Initial IMO Strategy stand any reasonable chance to be reached. Put another way, if fossil fuels continue to be used in a “business as usual” (BAU) fashion, the chances of reaching the GHG reduction targets look slim. In that sense, it is reasonable to expect that low-carbon and zero-carbon fuels could provide the necessary “quantum leap” that might give the quest for decarbonization enough momentum to reach the stated targets.

The subject of alternative fuels is vast, with many studies and projects examining the subject from various twists and angles, and also with specific real-life demonstration projects whose purpose has been to test such fuels in actual ships under specific scenarios in terms of technical and economic viability. See for instance, among others, the work of DNV GL (2018) in the area. For recent surveys on the decarbonization possibilities of such fuels and other technologies and measures, see Bouman et al. (2017), OECD (2018), (de Kat and Mouawad, 2019; DNV GL, 2015, 2018) and LR and UMAS (2020), among others. In this section and due to size limitations we provide only a flavor of some of the pertinent issues, by focusing on alternative fuels. We do this by drawing heavily from Psaraftis and Zachariadis (2019).

Natural Gas (NG) and Liquefied Natural Gas (LNG)

Natural Gas (NG) is about 90% methane (CH₄) and Liquefied Natural Gas (LNG) is about 95% CH₄. CH₄ is a GHG much worse than CO₂ in terms of effect on global warming. The Global Warming Potential (GWP) of CH₄ is not constant, but depends on the time horizon contemplated. Thus, for a time horizon of 5, 10, 20, and 100 years, CH₄ is respectively 116, 110, 86, and 34 times worse than CO₂ (Myhre et al., 2013; Howarth, 2014; Allen, 2014). It is clear that a time horizon of 100 years, being the lifetime of CO₂ in the atmosphere, is not very relevant in the climate change discussion, given the urgency of the situation as regards 2050. The above is an important point because using the proper GWP factor of 86 (instead of 25) immediately reverses all claims of LNG having a better GHG footprint than conventional liquid fuels. We refer to the GHG effect when LNG/ CH₄ escapes unburned to the atmosphere.

Indeed, when LNG is burned in a ship’s engine, it produces about 20%–25% less CO₂ than a conventional liquid fossil fuel, due to its lower carbon content. However, this assumes perfect combustion, which exists only in chemistry textbooks. In real life, a quantity of NG remains unburned and is emitted to the atmosphere together with the combustion exhausts. This escape, also known as methane slip, occurs in sufficient amounts in the vast majority of marine engines (4-stroke and 2-stroke dual fuel or Otto cycle-spark plug-engines). For all these engines, the methane slip—even according to the engine manufacturers’ stated numbers—renders them immediately worse than conventional liquid fuel engines, even when a mild GWP factor of 25 is used (Corbett et al., 2015; EU, 2016). For some latest high pressure combustion engines, methane slip is stated to be very small, but this refers more to the engine laboratory shop-test conditions and not necessarily to measured values in actual ship operation. In any case, multiplying even very small quantities of methane slip by 86, brings these state-of-the-art engines also at par to existing conventional ones, as is also discussed further.

The vast majority of gas engines on ships operate using the Otto cycle (as opposed to the Diesel cycle). Such engines have a published methane leak rate of 3–6 gr CH₄/kwh corresponding to a fuel loss of 2%–3%. Actual measurements invariably show a larger fuel leak rate (e.g., 6–8 gr/kwh in optimal operation and much higher multiples at low loads) (Corbett et al., 2015). These are LPDF (Low Pressure Dual Fuel) engines with pilot fuel and Lean Burn Spark Ignition (LBSI) engines. SINTEF (2017) has measured the methane leak of these engines at 6.9 gr/ kwh and 4.1 gr/ kwh, respectively with much higher values reported throughout the literature especially for LBSI engines. At these methane slip levels, either published by engine makers or independently measured, the GHG footprint of combustion is quite higher than conventional marine diesel engines, even using a 100-year GWP of 25. When a GWP of 86 is used, the GHG performance of NG combustion in marine engines becomes substantially worse than diesel or heavy fuel combustion. Furthermore, there is a limiting trade-off in that, if the engines are operated at a lower air to fuel ratio to reduce methane slip, then NO_x emissions increase exceeding Tier III limits. Already, exhaust after-treatment options are being discussed among regulators, involving methane oxidation/capture devices at the stack.

The latest type newly introduced gas engines (High Pressure Dual Fuel- HPDF) are promoted as zero slip (0.2% of consumption) by their makers (e.g., the ME-GI DF engine by MAN Energy Solutions) although independent references (Corbett et al., 2015) give

0.7 gr/kwh as more common (i.e., 0.4% of consumption). Although this is definitely a big improvement over the Otto cycle engines, we should remember that even just a 1 gr/kwh methane slip represents 86 gr/kwh of equivalent CO₂, and thus any GHG benefit over standard diesel engines is mostly lost.

The above discussion concerns only the LNG methane slip during combustion *at the engine*, which is only one of the areas of methane slip, perhaps the most minor one. Of course, its *lifecycle* methane slip should be considered as well. That involves possible leaks during transportation to consumer and, most of all, leaks during its extraction from the ground, which all currently are either ignored or severely understated from a proper GWP assessment. These leaks invariably occur and they can be considerable.

Hydrogen

What can be a more attractive fuel to burn than hydrogen? Pure hydrogen when burned emits no CO₂, and no SO_x. Thus, it is potentially a viable alternative fuel, provided the CO₂ intensity of its production could be addressed and provided that several technological and safety hurdles could be overcome. About 95% of the world's hydrogen production comes from reforming fossil fuels, mostly NG (Milne et al., 2006; Collodi, 2010). Obviously then the GHG issues described in the previous section on NG and LNG are also applicable to hydrogen, not including the CO₂ emissions in producing it from NG. The most common method to produce hydrogen is by steam CH₄ reforming whereby steam under high pressure, and in the presence of a catalyst, produces hydrogen and carbon monoxide and, with further "water-gas shift reaction," CO₂ and more hydrogen are produced. One ton of hydrogen produced in this process releases 9–12 tons of CO₂ (Collodi, 2010).

The CO₂ intensity of hydrogen production could be reduced by capturing and storing the released CO₂. Nevertheless, its origin, being mostly CH₄, results in the potent GHG effects related to methane's lifecycle (methane slip, etc). Clearly, the carbon footprint of hydrogen produced from NG is higher than that of HFO or MDO (DNV GL, 2018).

An alternative way to produce hydrogen is from electrolysis. Only about 4% of the world's hydrogen production uses that method. However, even this hydrogen cannot be considered as "green," since electrolysis requires large amounts of electricity, which usually comes from the grid. Only if this electricity originates from renewable sources (solar, wind, hydro) or even nuclear, could the hydrogen produced be considered carbon-free. About 55 kwh are required to produce 1 kg of hydrogen at an assumed efficiency of more than 60%. One kwh of electricity, when produced from a coal burning power plant, generates about one kg of CO₂. The US average is about 0.69 kg of CO₂ per kwh (DNV GL, 2015), while China and Russia produce most of their electricity from coal and most other countries from diesel oil. At an assumed worldwide average of 0.80 kg CO₂ per kwh, 55 kwh to produce 1 kg of hydrogen from electrolysis will emit 44 kg of CO₂.

As things stand, the technology required to enable the use of hydrogen as a marine fuel is still under development. Hydrogen is not an easy fuel to handle, transport and store. The boiling point of liquid hydrogen is –253°C (DNV GL, 2018) thus super-insulated (cryogenic) pressure vessels are needed for storage. Depending on the pressure, the size of the tanks needs to be 10–15 times larger than those of conventional liquid fuels (DNV GL, 2015). Also safety issues due to the volatility of hydrogen need to be resolved.

Ammonia

Ammonia (NH₃) is produced from hydrogen by adding nitrogen. Nitrogen is obtained from the air through liquid air distillation or an oxidative process where air is burned and the residual nitrogen is recovered. As such, in addition to the GHG effects of hydrogen and NG (being the primary source of hydrogen), the CO₂/GHG effects of nitrogen synthesis must be added to ammonia's lifetime GHG effects. The advantage of ammonia over hydrogen is that it can be stored as liquid in an easier temperature to maintain (–34°C) while, being a hydrogen carrier, its liquid form allows more hydrogen storage per cubic meter than liquid hydrogen itself (OECD, 2018). Ammonia used as fuel could offer GHG reductions to the extent that it is processed using renewable energy and is sourced from hydrogen made from electrolysis using renewable sources.

The Way Ahead

The picture of maritime transport in the future will be significantly shaped by the extent to which alternative low or zero carbon fuels that would provide the necessary "quantum leap" vis-à-vis BAU would be adopted. These fuels will have to become technically and (most important) economically viable if they stand any reasonable chance to be adopted in the future. This section addresses, among other things, how economic viability would be possible. As things stand, one thing is clear, to this author at least: Economic viability will not happen by itself and will depend upon a combination of factors, many of which are in the political arena. The exposition below borrows from Psaraftis and Zachariadis (2019) and Psaraftis and Kontovas (2020).

Nine years after the adoption of the Energy Efficiency Design Index (EEDI) in 2011, which is still (together with the Ship Energy Efficiency Management Plan- SEEMP) the only mandatory GHG emissions reduction measure, there is no doubt that the adoption of the Initial IMO Strategy in 2018 was a landmark decision. Achieving GHG emissions in 2050, which are at least 50% lower than they were in 2008, is a substantial and ambitious target that has to be taken very seriously by all involved.

At the same time, any hope that substantial GHG reductions can be achieved via improvements on EEDI is in our opinion grossly unsubstantiated. In a study conducted for Danish Shipping, Smith et al. (2016) showed, among other things, that the existence of EEDI versus a scenario in which there is no EEDI as we move to 2050 amounts to a GHG emissions difference of about 3%.

It remains to be seen whether the short-term measures currently on the table at the IMO will achieve a credible dent in GHG emissions. At the time this chapter was being finalized, no decisions on these or any other measures had been made. The COVID-19 outbreak in the spring of 2020 put a break on the speed of IMO regulatory decision making, and it is unclear whether the pandemic will have a real (positive or negative) impact on prospects for future GHG reduction. Our default assumption is that the IMO GHG reduction discussion will resume as soon as the COVID-19 situation is under control.

As stated earlier, there is still no sense of priority among the wide array of candidate measures, all of which are on the table. Market Based Measures (MBMs) have been put into the medium-term class (to be agreed upon between 2023 and 2030) *but only as a possibility*, even though the Damocles sword of a European Union (EU) Emissions Trading System (ETS) is looming, as will be explained further. There appears to be no sense of urgency for any MBM to be discussed at the IMO. Some industry circles seem to favor a bunker levy, but no one dares propose it explicitly at this point in time.

In December of 2019, the new President of the European Commission revealed that in the context of the “European Green Deal” (EU, 2019) shipping would be included in the EU ETS. To be clear, ETS is clearly an MBM. Thus far the position of the EU has been to align itself with the IMO process on decarbonization, and essentially refrain from acting on a possible inclusion of shipping into the EU ETS before seeing what the IMO intends to do on GHGs. The EU ETS is a major instrument in EU energy policy, covering electricity production and several other major industries (but not shipping). The European Commission has been closely monitoring the IMO process, starting from what is agreed on the initial strategy in 2018 and all the way to 2023. Until recently, the Commission had refused to take the ETS option off the table or even to specify what would trigger action on its part. However, as of December 2019 this has changed, and the European Green Deal clearly points to the ETS path for shipping.

One week after the European Green Deal was announced, as many as eight shipping industry organizations to IMO (ICS, BIMCO, WSC, Intertanko, Intercargo, Interferry, CLIA, and IPTA) publicly announced to IMO a to be jointly funded project for a 5 billion USD fund that would be used to finance R&D for technologies and fuels toward decarbonization. This would be raised by a 2 USD/ton mandatory surcharge on bunker fuel (ICS, 2019).

This proposal, which had actually been prepared by the shipping industry for some time now but essentially kept in the drawer until its recent public release, is not labeled as an MBM and in fact it is hardly an MBM. It is clear that two dollars per ton will not reduce GHG emissions, either in the short run or in the long run. *A fortiori*, any link between the R&D that could be conducted going forward and any actual decarbonization that might occur as a result of this R&D is sketchy at best. The proposers state that the R&D fund would only cover applied research and not commercial development of fuels and other technologies, which would be left to other stakeholders, such as shipbuilders, engine manufacturers, energy producers, ports, etc. At the same time, the proposers state that their proposal is not intended to frustrate or delay the development of an MBM should there be consensus for this among Member States, and that the architecture of their proposal could be used should the IMO proceed with a levy (implying that this would be their preferred MBM).

Whatever the case, the European Green Deal and its link to shipping decarbonization via the EU ETS has suddenly upgraded the role of the EU as an important player in the IMO process. After the news was announced, the IMO Secretary General rushed to defend the overall IMO approach and indicated his willingness to talk to the European Commission and Parliament. How these discussions will evolve remains to be seen. In the current IMO agenda on GHGs, the European Green Deal is still below the horizon, at least for the time being.

Substance-wise, our position is that the main plus of the European Green Deal, as regards shipping of course, is the increased pressure it can exert on the IMO to move faster, and that a levy on bunker fuel or on carbon emissions would be a far better MBM than ETS in the quest to decarbonize shipping. For a discussion of the relevant issues see Psaraftis (2012), Psaraftis and Lagouvardou (2019), and Lagouvardou et al. (2020).

Irrespective of the fact that MBMs are not up for discussion at the IMO in the foreseeable future, one idea that might be worth considering would be to impose a significant bunker levy at a global level. By significant we mean not 10 or 20 USD per ton, as is being occasionally contemplated by industry, but at least one order of magnitude higher. To put it very simply, if society truly does not like fossil fuels, or any other fuel that produces GHGs (and this includes LNG), and cannot, for obvious reasons, mandate their outright ban, society should at least try to implement the “polluter pays” principle by internalizing (even partially) the external costs of GHGs. The only way to do so is by putting a significant price on the fuels that produce these GHGs. Conversely, and so long as these fuels are affordable, there is no doubt that they will be used. All the debate on LNG, hydrogen, and other alternative fuels (see section, The Drive to Decarbonize Shipping above) critically hinges upon the economic dimension: we would like to know not only how much GHGs these alternative fuels would avert, but also what is the cost of producing and using them. Conversely, and barring a technological quantum leap, for as long as these alternative fuels are not viable economically, they will not be used. In turn, and as long as fossil fuels are cheap, they will be used.

We basically think that a substantial bunker levy would be the best (or maybe the only) way to induce technological changes in the long run and logistical measures (such as slow steaming) in the short run. In the long run, it would lead to changes in the global fleet toward vessels and technologies that are more energy efficient, more economically viable and less dependent on fossil fuels than those today. In that sense, it would have the potential to drastically alter the face of maritime transport. However, as things stand, and mainly for political reasons, the adoption of such a measure is considered as rather unlikely. If proposed, it will likely encounter the resistance of many IMO member states, with the US leading the pack, at least as things stand.

So to conclude, it would seem that the future of maritime transport, and specifically the direction it will take in the years ahead, critically depends on whether or not maritime policy makers can find a way to make the world shipping community adopt the bold measures that are necessary to incentivize the viable development and use of alternative low or zero carbon fuels.

While maritime transport is a mode that obviously depends upon seas and oceans, it possesses distinctive and critically important territorial dimensions. Ships have to exchange their cargoes and passengers at sites on land, and it is with terrestrial-bound customers that their revenue-generating business depends. The territorial dimensions of maritime transport are therefore of fundamental importance.

Ports are the points of contact between ships and land. Ships require sites that they can access and where they can dock safely. Accessibility and safety are the most fundamental requirements of a port. Ships must also be able to load and/or discharge their cargoes efficiently. This requires port infrastructures involving quay walls, terminal space, and equipment that are capable of achieving ship turnarounds with the minimum of delays. From a shipping perspective ports are land-based facilities that are absolutely essential to maritime trade.

Ports also serve wider functions on land. They are essential components of supply chains that link producers and consumers. For many supply chains the maritime link may be the longest spatially or timewise, but the landward connections between the port and the original producer or final consumer are the connections that account for the highest costs and present challenges for on-time performance. Landward links from ports have become a critical concern for customers and represent one of the most difficult challenges in global supply chains.

This article examines these two territorial dimensions of maritime transport. The first considers the port as a land site that carries out specific functions for shipping. It is an urban land use with a very distinctive character, one that has undergone significant change. Because it occupies waterfront sites it frequently enters into conflict with other land uses. The second dimension is its regional importance. Ports serve markets, and these are becoming more extensive and competitive in many cases. Ports, and the actors who comprise the port community, seek to extend and strengthen the linkages, so that the port region, or hinterland, becomes a means of securing traffic and strengthening competitiveness.

The Port as a Land Use

For maritime transport a key territorial requirement has always been that of a site where ships can shelter and load and discharge their cargoes with safety and efficiency. Favored port sites were where natural features provided protection from storms and where there was sufficient depth of water to allow access. Over time, and dependent upon traffic growth, physical infrastructures such as wharves were built to facilitate loading and unloading from ship to shore and artificial barriers were constructed to provide protection. The port area became a distinct zone but was integrated within the general urbanized area. The trade passing through generated economic multipliers due to the manpower employed in the port itself, in the manufacturing industry that processed goods shipped through the port, and in the transport related businesses that managed its trade and commerce. It is not surprising that many port cities became major urban centers, such as London, Hamburg, Marseilles, Genoa, New York, New Orleans, Shanghai, and Tokyo.

Over time ships changed from wooden craft powered by sail to steel ships powered by fossil fuels. The repercussions of these technological developments were significant particularly with regard to speed, but their impacts on ports were not substantial because the capacities of ships remained constrained by the ability of ports to load and unload cargoes efficiently. Port operations were labor intensive. Freight was brought from storage sheds to dockside using animal and human labor; the goods lowered by sling and pulleys into ships' holds, wherein gangs of men had to secure the freight, an extremely dangerous procedure. All kinds of cargoes were involved, from raw materials to packages and barrels, of different shapes and sizes. Loading and unloading took time, and

vessels were laid up in port for weeks. Thus there were diseconomies of scale in shipping since increasing the size of the ship would result in longer port calls and still fewer potential revenue-generating trips per year.

The most important factors precipitating the changes were market conditions and the mechanization of port operations. The earliest market sectors to change were the bulk trades, because the global economic and population growth that occurred after the end of World War II generated increased demands for liquid bulk (oil) and dry bulk (coal, iron ore, and grain). Because these were products that could be handled more easily than others, using pumps and conveyer belts, they permitted scale economies to be realized, and in both sectors vessel size increased dramatically. In 1951 the largest tanker had a capacity of 20,000 DWT (deadweight tons), while the typical size of a dry bulk ship was 10,000 DWT. By the late 1970s maximum tanker size had increased to over 300,000 DWT. The growth of dry bulk carriers has been slower but the maximum size by the 2010s has reached 400,000 DWT.

The transformation of general cargo handling in the ports of the world remained largely unchanged until the mid 1960s after the introduction of the container. Its concept may have been simple, but the economic consequences of the container have been profound (Levinson, 2006). Standardizing the unit load allowed rapid transfers of cargo across quay walls by cranes that slot the containers one on top of other in the holds of ships. The storage of containers and their repositioning in the terminal could now be mechanized too. Because of the mechanization, vessel turnarounds could be achieved far more rapidly than before, so that instead of ships spending weeks in port their turnarounds today are measured in hours. As with the bulk trades the size of container ships increased as a result the increased efficiency of handling. The first cellular ships of the early 1970s had capacities of 1000 TEUs (20 foot equivalent units). Size increased to 5,000 TEUs by the late 1980s, 10,000 TEUs by the end of the 20th century, and 20 years later the largest container vessels exceed 21,000 TEUs.

As much as the increasing size of ships was made possible by growth in international trade and economies of scale, it must not be forgotten that ports have played a significant role. It has been their ability to exchange cargoes between land and ships more efficiently that made the growth in vessel size possible. In turn ports were transformed. Larger capacity vessels require deeper channels, longer berths, and more storage space as well as more expensive handling equipment. Existing docks sites were rarely suitable, and so new larger sites had to be developed and equipped. In most cases new terminals were built on greenfield sites some distance from the port city. The effects of the changes have been to change the character and functioning of ports themselves and to alter the dynamics between ports and the cities.

The Changing Character of Port Sites

The ability of ports to respond to the growth of traffic and the increase in the size of ships have required significant capital investments. While the shipping industry itself has had to invest heavily in new vessels, a great deal of the costs of has been borne by the ports themselves. Satisfying this demand represents significant capital costs for port authorities, either through relocation to extensive sites adjacent to deep water or for dredging. There are differences between bulk and general cargo concerning the capital costs of developing new terminals. This is because they possess different operational, ownership, and organizational characteristics. Bulk shipping involves freight that is handled in large quantities at terminals owned or leased by corporations whose shipments are components of industrial supply chains controlled by the corporations. They use ships that are owned or leased by the same corporations. Fluctuations in traffic are shaped by broad market conditions. In contrast, general cargo (largely containerized today) is transported by independent carriers that operate between ports on regular liner services, who charge rates according to demand, and serve a wide range of customers from small shippers to giant retailers. The terminals are built by port authorities who, in some cases operated the terminals, but more frequently lease them to terminal operators. There is a high degree of uncertainty in this business: the shipping lines are footloose and have freedom shift services to competing ports, and the terminal operating companies have little control over traffic volumes. Port authorities have to attract carriers in order to secure business and have to invest heavily in terminals with no guarantee of success.

The capital requirements for port development raise a number of questions that have led to different solutions. The first set of questions arises out of port governance (Ng and Pallis, 2010). Up until World War II, ports in most countries were owned by central governments and operated as a public service. The costs of providing the services and the ability of a public authority to manage a resource in the competitive field of containerization resulted demands for reform in port governance. The UK and New Zealand opted for total privatization; many others adopted a system of commercialization while retaining nominal public control. Others, under the control of municipalities such as those in Northern Europe, remained largely unchanged. Academic studies of the success of port reforms are numerous, but the results are inconclusive. The major issue is that as much as port reform has led to greater efficiencies, the capital requirements still require financial support from national governments, many of which are reluctant to undertake either because of the demands other more popular projects, or because of uncertainties of outcomes. In some countries, such as Canada, where port reform took place 20 years ago, the issue of privatization or other models of governance are presently under discussion.

A second issue concerning port expansion is that of public acceptability (Hoyle, 2000). Port activities now take place in relative isolation from their host cities. Their sites are extensive and located beyond the daily routine movements of most residents. In addition, they are gated and fenced off, because of international regulations on port security. Many residents see ports in a negative light because they are perceived to cause pollution by the refineries and smelters in the port zones, and they generate traffic that clogs urban highways. An important additional factor is that the direct benefits of jobs that tied the port to the city in the past have diminished. The number of dockworkers has fallen by over 90% in some ports, and although the remaining unionized workers are well-paid, there is evidence that other workers dependent on the ports, such as warehouse workers and truckers, have seen their

salaries decline in constant dollars over the years (Hall, 2009). It is no surprise therefore that the port is no longer seen by many citizens as a positive contributor to urban life. They see governments being called upon to invest in new infrastructures to accommodate the longer ships that require deeper channels, when there are other more pressing urban issues.

A result of these concerns is that port expansion and development especially in Europe and North America has become a time-extensive process. Not only have the commercial justifications for port projects are subject to greater scrutiny, but are also exposed to rigorous environmental and social acceptability assessments. Research on recent projects reveal that several have been abandoned because of negative assessments, such as Dibden Bay in the case of Southampton, while others have required 10 years of evaluation in the case of Deurganck Dock of the Port of Antwerp, while that of Maasvlakte II of the Port of Rotterdam took 20 years. If this trend continues, it may result in port congestion as ports lose their abilities to cope with trade growth. It also means that by the time projects are realized market and technology may have changed, thus threatening the relevance of the project. The situation is very different in China and many other developing economies, where projects are completed without comparable delays.

The Port as a Regional Hub

The container has not only allowed ports to achieve high levels of productivity, but has greatly facilitated its transport beyond the port gates. Intermodality has been one of the great beneficiaries of containerization. Other modes of transport can combine to extend services across ever-wider market areas, because the container, as a standard unit of freight, enables relative seamless interchanges between the modes. In this way container ports have opportunities to extend their market areas inland and compete with other ports for business. Ports that can generate more volumes enhance their attractiveness for the ocean carriers, which in turn offer customers a wider range of services that then becomes a competitive advantage over other ports. Ensuring market dominance over a productive hinterland has become a key commercial objective for ports, and this has led academics to explore the process and challenges of what is referred to as “port regionalization” (Notteboom and Rodrigue, 2017).

Port regionalization implies not only the attempt to manage and extend the market coverage of ports, but is also tied in with a problem of managing the growth of container traffic in the ports themselves. In many ports traffic growth is causing congestion. This becomes evident at the gates of entry and exit for trucks delivering and picking up containers, in the roads adjacent to the terminals and along corridors through cities. A wide range of solutions are in place to try to resolve congestion at the port gates. These include requiring trucks to make appointments, reducing charges at off-peak times, and extending hours of operation. The results reveal varying degrees of success. One problem with using time as a means of managing truck flows is that truckers are also dependent upon the hours of operation of the warehouses and logistics centers whose schedules may be more restrictive.

More general and extensive solutions to port and urban congestion revolve around promoting other modes of transport, especially rail, and where possible, inland shipping. Effecting a modal transfer is not always simple, since may give rise to operational and issues and involve commercial viability. Even where rivers are navigable the port has to find space for berths required for transferring containers to barges. In the case of rail transfers there are issues of exchanging containers between the port terminals and rail freight yards as well as the interest and ability of the railways to offer efficient services. The result is that solutions are varied and involve different sets of actors. In the case of European ports the lead has been taken by some ocean carriers who operate dedicated rail services from Rotterdam, Le Havre, and Hamburg to inland markets. In the case of barge transfers the ports have played a role, either by subsidizing barge services, as in the case of the Port of New York–New Jersey (which failed after the subsidy was terminated), or where port authorities form alliances with smaller inland ports to organize barge terminals and coordinate information exchanges as is the case of the port of Rotterdam.

A feature and concept closely related to port regionalization rationalization is that of dry ports (Witte et al., 2019). These are inland centers linked by dedicated rail service to ports that carry out many of the functions of ports, including customs clearance. Because they have more space they can relieve congested ports, while still ensuring that containers can arrive on time in ports ready for loading, and can store containers after being off-loaded from the ship. They also serve as a means of diverting traffic in hinterland regions from competing ports. Examples include the Dutch inland port of Venlo on the border of the Ruhr, the inland port of Zaragoza established by the port of Barcelona to divert potential traffic from Valencia as well as capture transborder traffic from southern France, and Front Royal, referred to as Virginia Inland Port, established by Virginia Ports Authority to divert Mid West traffic from Baltimore to Norfolk. Dry ports tend to be established by port authorities or private terminal operators.

Academic research indicates that port regionalization rationalization combines three levels of activity. First is that of the physical transport infrastructure involving all modes between the seaport and interior markets. Second are the service networks that refer to the direction, capacity, and frequency of transport connections and the actors that operate and manage the transport systems. Third are the flows of freight along the logistics chains that connect the port with customers across the hinterland, which requires understanding of the actors, their roles and activities that manage the flow of goods.

Future Challenges to Ports and Their Hinterlands

As they enter the third decade of the 21st century ports are confronting challenges that have the potential to modify and even destroy certain features that are taken as granted today. Four basic issues are considered. They are not unique to ports but they are likely to require adjustments or provide opportunities that are distinct. Detailed exploration of these topics is impossible, rather a brief

indication of what they are and how they might impact ports is undertaken. The order in which they are presented in no way reflects their importance.

The Energy Transition

There are growing concerns world-wide about burning of fossil fuels and contributions to the increasing levels of CO₂ in the atmosphere. There are policies in place internationally that are calling for a reduction in their use. For ports, this issue has two dimensions. First is the fact that liquid bulk, especially crude oil and refined products, represents a very important traffic. Many ports regard this as a cash cow, since the revenues generated are realized without significant costs to the port authority. Coal is another product that is threatened, especially since coal-fired thermal stations are being closed down. A decline in traffic would affect the financial health of ports, and in the long run present challenges and opportunities for the possible re-use of liquid bulk terminals. Alternate energy products might be considered, liquified natural gas and liquified petroleum gas are possible substitutes, but there are major concerns about their social acceptability close to urban centers.

The second dimension of fossil fuels is their use within the port area. Already many ports offer “cold ironing,” where ships in port can turn off their diesel power units by being attached to port electric outlets. There is also a growing trend for the replacement of diesel-powered equipment within the port, such as cranes and vehicles, by electric motors. For the port authority and terminal operators this represents a considerable financial commitment.

Automation and Digitalization

The modern port achieved its present importance by facilitating world trade through mechanization. Today it is on the cusp of further transformation as a result of automation. Indeed, evidence is already accruing that the digital revolution has begun. One of the trends in container operations is the automation of terminals. Mechanization of ports reduced port labor requirements very significantly, but the tasks of many aspects of port terminal are already digitized, with tracing and tracking of containers from the moment they enter the terminal, as well as their ultimate stowage position on board the vessel. Further automation is already evident in some ports. This includes the use of autonomous machines that physical remove arriving containers from trucks and rail wagons that move them and lift them to storage lines, and, when required, load them on board ship by gantry cranes. Automated terminals now exist in some ports, such as Rotterdam, Singapore, Shanghai, and Los Angeles. Evidence suggests that full automation may not be appropriate at present because of costs for smaller ports or those where traffic is variable with peaks and valleys. On the other hand, the present high capital costs may be expected to be lowered over time. The issue with dock labor remains a challenge.

The container port is a nexus of information. Documentation is essential, but it has many sources (shipper, consignee, insurance company, transport providers, customs and excise, homeland security or equivalent, terminal operators, port authorities). What information is required differs. The result has been the gradual replacement of paper documents and faxes with electronic data interchange. The process may have been speeded up but it is still cumbersome. Estimates suggest the cost of information handling represents 15% of all transport costs. Blockchain technology is being proposed as technology well suited to large networks of disparate partners. As a distributed ledger technology, blockchain establishes a shared, immutable record of all the transactions that take place within a network. It then enables permitted parties access to trusted data in real time. In late 2018 IBM and A.P. Moeller-Maersk formed a partnership to exploit blockchain with several ports.

Cybersecurity and Ports

Ports, their customers, and related partners all use information systems and communication technologies for equipment operation, cargo movement and tracking, business operations, and security. These not only control the operation of terminals but are also used to monitor security, handle business functions such as invoice preparation and billing. There are different systems in place among the actors. This makes the port community prone to malicious activities and software errors because there are so many points of entry into the systems. In 2013 Maher terminals, a major terminal operator in New York, experienced difficulties in switching between old and new computer systems and the result brought the terminal to a standstill and had impacts on other terminals in the port as well as deliveries throughout the north-east United States. In 2017 Maersk shipping line was attacked by hackers that interrupted operations at 73 ports around the world. It cost the company \$300 million to recover from the attack. Cyber attacks have also been reported in the ports of Barcelona, Long Beach, and San Diego.

There are growing calls for better training, regular vulnerability inspections, and in particular, contingency plans. The International Maritime Organization is preparing regulations on cyber security.

Ports and Climate Change

Climate change is claimed as one of the greatest challenges to humanity. Occupying sites at the interface of land and water, ports are vulnerable to environmental impacts produced by changing climate (Ng et al., 2015). Higher sea level, increased storminess, longer periods of high temperatures all have the potential to influence ports and cargo handling. The difficulty, however, is that the changes are not uniform across the world. In some locations it is land that is rising that is resulting in local changes of sea level, in others it is increasing droughts that is the major climate change impact. Consequently, climate change must be addressed at the local level,

with the risks assessed and mitigation measures applied case by case. Rather, maritime transport as the greenest of transport modes has the opportunity to improve its position in the global transport industry if the existing black marks of using heavy oil as fuel is changed.

Introduction: What is a Port?

A port is generally understood as the interface between sea and land, where goods change *mode of transport*, for example, from ship to truck or rail and vice versa (Fig. 1). To operate safely, a port needs to be protected, or *harbored*, from the elements of nature (waves, winds, currents) by such things as breakwaters and windbreakers, but also by essential port services like towage, pilotage and line-handling which assist the ship to berth and start in safety its cargo-handling operations. The latter operations require a wide spectrum of port equipment such as ship-to-shore cranes, straddle carriers, reach-stackers, forklifts, and more.

Fig. 1 shows a part of the historic Port of Brindisi, South Italy, at the turn of the previous century (c. 1920). The train would arrive right at the waterfront—something very uncommon at that time—in the true sense of *intermodality* (see below), 100 years before the term was invented (The train, coming from London and Paris, would bring to Brindisi “la valigia delle Indie,” that is, the diplomatic bag (actually a trunk) and other mail and documents heading for India. Crossing Suez was great fun and an adventure, but the ladies had to be careful with the scorching sun. Thus, cabins had different prices with the most expensive ones being the *posh* (i.e., Port-Out-Starboard-Home). At the very same spot, Phileas Fogg and Passepartout (Jules Verne: *Around the World in 80 Days*) were waiting to board P&O's m/s Mongolia. Fogg was worried of a delay but Passepartout was reassuring him that, opposite to sailing ships, steamships were never late!).

Although the general public may understand the importance of ports (and shipping) for trade, growth and prosperity, most people have never visited or seen a port at close distance. Rather, the impression people have of a port is usually one of an exotic spot, of romanticism, adventure or organized crime. Cinematography has helped a lot in creating this impression: A beautiful account of the “waterfront” can be enjoyed in Elia Kazan's 1956 masterpiece “on the waterfront,” with Marlon Brando, or Mike Newell's 1997 drama “Donnie Brasco,” with Al Pacino and Johnnie Depp.

To put things in perspective, a port can be anything from a sheltered stretch of sea, protecting a handful of fishing boats somewhere in the South Pacific; a block of cement in a small Greek island, on which a passenger ferry would lower its ramp to disembark passengers; a buoy onto which a tanker would moor to offload its oil through a pipeline; a finger-pier alongside which a bulk carrier would unload its coal on a conveyor belt; a *cool port* (i.e., a refrigerated facility) in Latin America exporting fruit to Europe; a mega-yacht marina in Monaco or Nice, or just a water-taxi that would disembark passengers from a cruise ship

Figure 1 Port: the interface between land and sea.

anchored in the middle of the sea, outside Amalfi, in the absence of any berthing infrastructure at the picturesque village of South Italy. At the other end, there is the mindboggling Yangshan Deep Water Port (of Shanghai), handling 40 million containers a year, or the equally impressive industrial complex of the Port of Rotterdam, running for 40 km along the river Meuse to the North Sea, comprising in its domain a *cluster* of thousands of companies, from the large refineries of the oil majors, to the small paint shop, inconspicuously hidden under an abandoned bridge, next to a pub.

The chapter is organized as follows: The following section discusses the important city–port relationship and the way ports have developed and relocated over the years, in parallel with increases in trade and ship sizes. The complexities in port management are also discussed here, as well as the new phenomenon of inland terminals (dry ports), aiming to relieve seaports of congestion pressures and improve on seaport efficiency. The section thereafter presents the port landscape before the arrival of containerization. Port labor is discussed here, and the need for economic reforms as a result of the new, intensified, competition among ports. The section concludes with a note on port finance and the increasing participation of the private sector. The chapter continues in its next section with the *container revolution* and the impacts and radical changes this development brought about on the emergence of *hub-and-spoke* systems in global distribution; containership sizes and port labor productivity. Diseconomies of scale in ports, due to the emergence of mega-ships, are also discussed here. The final section concludes.

The City-Port

In the past, and whenever possible, cities were built along the banks of rivers and so were their ports. The “city-port” was the epicenter of commercial activity and trade. Historical examples are those of Antwerp, Hamburg, London, Manchester, Paris, Ghent, Bruges, Amsterdam, Rotterdam, Bordeaux, Nantes, Rouen, and many others. The economics of the city-port concept were simple: The port is an essential element of trade; trade requires transport; and transport costs money; sometimes a lot, particularly in the earlier days and in the absence of “transport and logistics” as we understand them today. Thus, minimizing transport costs was essential and what better way to achieve this than building ports close to cities.

As trade was increasing—and together with it the size of ships—, ports needed bigger and deeper *turning basins* and *approach channels*, so that ships could approach and maneuver safely. In addition, increasing trade necessitated more storage areas (warehouses) in the port, and these either did not exist, or their (opportunity) cost was very high given the alternative uses of port land in a city (housing, commercial, etc.). Thus, ports started to relocate downstream to river estuaries. Whenever this was problematic, artificial canals were dredged, like the Nieuwe Waterweg (New Waterway) of Rotterdam.

Downstream, space was ample and water depths sufficient to accommodate the larger and larger ships without the need for too much dredging which is expensive, often technically difficult, and above all environmentally impactful: the siltation of rivers brings with it soil which is polluted from agricultural fertilizers (of cultivations irrigated from the river), or cooling-water sewage from industrial activity. Disposing of dredged materials is subject to very strict laws in most countries and this makes dredging an even more difficult decision. Notable downstream examples are Bremerhaven (Bremen), Le Havre (Rouen), Maasvlakte (Rotterdam), Zeebrugge (Bruges), Le Verdon (Bordeaux), Tilbury (London), Liverpool (Manchester), and Nantes St. Nazaire (Nantes) among many others.

Thus, old city-ports were abandoned and many of them still remain so. Others have been beautifully rehabilitated and have become the most exclusive residential; commercial; business; and entertainment areas of the city. Notable examples include the Docklands of London, the Koop van Zuid in Rotterdam, Hamburg’s HafenCity, the Porto Antico of Genoa, or the Vieux Port of Marseilles (Fig. 2).

Figure 2 Old port areas rehabilitated (clockwise from upper left: Rotterdam, Hamburg, Amsterdam, Genoa).

Port Planning

In most cases, moving downstream has allowed ports to overcome the problem, albeit only temporarily. Up to the economic crisis of 2009, trade was increasing at an average annual rate of 8%, while the infrastructure of ports and terminals, once built, would remain fixed for many years, if not decades. Thus *port planning* has always been one of the greatest challenges of a port administration.

If one asks an ocean carrier how big a port should be, they would immediately reply “as big as possible.” Apparently, a carrier would not want to wait even for a minute if they could help it, and it has been established (see below) that, at a port capacity utilization of around 75%, congestion starts to set in.

If instead one would ask the same question to a port manager, particularly one responsible for his “bottom line,” the answer would be “as small as possible.” Obviously, he would love having ships queuing up outside his port, like the good old times, if he could help it.

As usual, both need to put some water in their wine and compromise: too little port capacity is as bad as too much: The first would cause congestion and loss of custom to competitors; the second would be wasting scarce taxpayer money. In other words, the ship cannot wait, nor, however, can the port continue spending taxpayer money so that the ship does not do so. This is particularly true in increasingly commercial activities, such as those of transshipment container terminals, whose impacts are not localized at the economies that have borne the brunt of the investment, but are dissipated throughout the supply chain, from the country of origin to the country of final destination of the transported goods.

Port Terminal Operations

Port land in downstream ports is available but not unlimited. Moreover, land at seafronts has also a lot of alternative uses—recreation; fishing; residential—and thus high opportunity cost. And although with the arrival of the container demand for conventional warehousing space may have declined, the number of containers arriving at the port—both for export and import—has been increasing steeply. In most ports with scarce port land the solution has been to stack them high, that is, stack containers on top of each other. This, combined with a need for highest efficiency in terminal operations—the result of intensified terminal competition amongst neighboring ports—has led to a number of interesting optimization or, rather, minimization, problems in *operations research* or *management science*. Some of them are briefly discussed in what follows.

As usual, the thing to “minimize,” that is, the problem’s *objective function*, is costs. In our case, such costs relate to “unproductive moves” of containers and of cargo-handling and transport equipment in the port. These movements, obviously, cost time, fuel for cargo-handling equipment (e.g., straddle carriers) and other energy costs; labor; and environmental impacts. Listed below are some of the optimization problems that need to be addressed, piecemeal or jointly, by the management of a port terminal:

- Containers that arrive at the port, either to be exported or imported, cannot be stowed anywhere at will. To minimize distances travelled by handling equipment (straddle carriers and trucks, for example), export containers are usually placed in designated areas closer to the ship and import containers closer to the gate.

- An export container, to depart shortly, should be placed as high up as possible in the stack, preferably with no other container on top of it. In the opposite, *reshuffles* would be necessary, if the top containers depart later. Moreover, reshuffles increase dramatically with the height of the container stack.
- Special containers, such as reefers and containers carrying dangerous goods, should be stowed in designated areas; this is also the case when stowing containers in ships.
- In large busy terminals, hundreds of trucks arrive, often simultaneously, to pick up containers. This may create severe congestion at the gate, on the motorway, or at parking areas outside the port.
- With regard to export containers, these must be loaded in a certain way, according to a *stowage plan*. Containers heading for the same destination port should be stowed close together.
- Filling up the bigger ship in Asia is easier said than done. To do so, the ship has to call at more Asian ports than what her size would warrant, often picking up containers at random and at short notice, without due consideration to the importance of proper stowage planning. As a result, ship- and terminal stowage planning at the other end (Europe/North America) often becomes a nightmare and this is one of the reasons carriers are investing in their own *dedicated terminals* (Haralambides et al., 2002).
- To ensure the right vessel stability, weight distribution should be observed and heavy containers should be stowed below deck as much as possible.
- Dangerous containers should be segregated from the rest.
- Shipping alliance members have their own bays on the ship which adds inflexibility and higher complexity to the stowage problem.
- Same as at the terminal, stowing containers onboard ships should minimize *rehandles*.

Inland Terminals (Dry Ports)

In spite of all this, and of terminal automation advances which often approach the limits of science fiction, the problem remains: container throughput increases much faster than what ports can handle, at least at the level of efficiency expected by their clients, whose ships become bigger and bigger. Concentration of cargo at main hubs does not make things easier either. A reversal of trends can thus be seen as of recent. From the earlier era when ports were obliged to move downstream to find space, ports now look back at the hinterland to find the additional space they require. Inland terminals (or dry ports) are therefore mushrooming, connected to the seaport by rail, road or inland waterways (Haralambides and Gujar, 2011, 2012). As such, inland terminals are usually developed close to railway and motorway junctions, to facilitate the transfer of containers between modes of transport, favoring, to the extent possible, the more environmentally friendly modes like rail and inland waterways transport.

Depending on population density and level of economic activity in the seaport's hinterland, inland terminals have often been described as *satellites* (or extensions) of the seaport: These terminals are located at close distance to the seaport and are often managed by it, at least in their initial stages of development. Such arrangements are typical in densely populated Europe. Oppositely, where distance to the seaport is the main issue (e.g., North America or China), *long-distance intermodal rail hubs* are the preferred solution.

An inland terminal is not much different than a seaport apart from the lack of a seafront! Stacking yards, cargo-handling equipment and gates are all similar to those of the seaport. As the purpose of the inland terminal is to *feed* the seaport with containers at the right time, thus by-passing the need for storage and extra handling at the seaport, the presence of customs authorities at inland terminals is of importance. The same is true for import containers which should speedily leave the seaport for the inland terminal without spending time in the seaport's main stack. In this way, the inland terminal serves another important function, that of an *inland distribution center*.

In all cases the role of the *Port Authority* (PA)—the autonomous body which manages the seaport—is crucial. As it is further discussed below, PAs are assuming an increasingly enterprising role as “stakeholder managers,” extending their “gates” to the hinterland, as further out as possible, so as to also widen their catchment areas. To do this, the “*intelligent port authority 4.0*” needs to smooth out supply chain bottlenecks among ships, terminals, customs authorities, and hinterland transport, storage, and distribution. The seaport of today understands, in its supply chain manager role, that it is now supply chains and not ports that compete for custom.

Such a role requires modern management practices and the transformation of the PA from a government dependency to an entity operating under increasingly commercial terms. Often, “stakeholder management” is an extremely frustrating exercise in view of conflicting interests, particularly when such “stakeholders” sit in the governing or supervising boards of port authorities.

Ports Before Containerization

In the earlier days (up to the beginning of the 1960s) *general cargo*, that is, manufactured and semimanufactured goods, carried by liner shipping, was transported, in various forms of packaging (pallets, boxes, barrels, crates, slings), by relatively small vessels, known as general cargo ships. These were *twin-deckers* and *multideckers*, that is, ships with *holds* (cargo compartments) in a shelf-like arrangement where goods were stowed in small prepackaged consignments (parcels) according to destination (Fig. 3).

This was a very labor-intensive process and, often, ships were known to spend most of their operational time in port, waiting to load or discharge. Extensive warehousing facilities were in this way also necessary to protect goods-in-waiting from the elements of nature. This required lots of space which often did not exist in bustling ports, making port work even more labor-intensive.

Figure 3 Multipurpose, general cargo vessels.

Unpredictability of ship arrivals made *congestion* a chronic problem in most ports, raising the cost of transport and hindering the growth of trade. Equally importantly, erratic and unpredictable cargo movements (and consequently port work), obliged manufacturers, wholesalers and retailers to keep large stocks. As a consequence, warehousing and carrying costs were adding up to the cost of transport, making final goods more expensive and, again, hindering the growth of international trade.

Port Labor

Seafaring was great fun in those days [sic]—seafarers were exploring foreign ports and cities in a multitude of different ways—, but the same cannot be said for the *casual* labor ports were employing, which was rather ill-considered and looked down by society. And this is why: As a result of the unpredictability of port work, port management could not possibly employ permanent staff, paying them while idle, and waiting for the next ship to arrive, if it ever did. Yet, once in port, cargo had to be unloaded quickly, so that produce would not spoil. Labor was thus *casual*, that is, employed for as long; as much; and whenever required. This is how it worked: Each morning, a number of *dockers* would present themselves to a union foreman, often a mobster, and he, on the basis of certain “criteria” that had more to do with *natural selection* rather than anything else, would thumb-in the youngest, the strongest, the favorites of the union, or those prepared to return a kickback to the union (to indicate this “preparedness,” a docker would put a toothpick behind his right ear). Those dockers not selected would return to their “locales” [sic] and indulge in whatever it was they were indulging in. As a result of this type of (casual) employment, ports were ill-famed and often centers of organized crime.

Port Competition and the Need for Port Reforms

Ports had no incentive to change; on the contrary: in the former times of import substitution policies (protectionism), inefficient ports were seen by many as effective nontariff barriers to trade. It has sometimes been argued that import-competing domestic producers had strong vested interests in the continuing existence of inefficient ports, as this offered them effective protection. Such producers could also be effective lobbyists and influential members of pressure groups that resisted port reform.

Moreover, ports were run by a public body—a municipality or a government department—while their *hinterland* (i.e., their catchment area) was *captive*: In other words, due to tariffs and other trade restrictions, national borders and lacking infrastructure, ports enjoyed considerable monopoly power; that is, cargo destined for, say, Italy would in all likelihood land at an Italian port, as close as possible to the final consignee. Thirty years ago, and as a result of “captive” port demand, forecasting port capacity was a fairly straightforward exercise, and a popular one at that, among students: population, GDP and trade data, together with a simple regression model, would easily do the trick with some excellent results. **Fig. 4**—still used by modern day port consultants—tells us that a GDP multiplier of 2.2 means that a 1% increase in national GDP would on average lead to a 2.2% increase in the country’s containerized imports. The same graph shows the dramatic decline in trade since the 2008–9 economic crisis. Localization vs globalization of manufacturing; protectionist policies; populist politicians; the US–China trade standoff; contempt for cheap consumerism and similar trends have all contributed to this.

Two things have changed this picture since: the development of extensive land transport infrastructure on the one hand, and containerization and the “through transport” concept on the other.

Figure 4 The GDP multiplier. *Source: IMF; BCG.*

Development of Infrastructure

Europe, for instance, dilapidated by a ruinous WWII, was being rebuilt, and what better way of doing this than developing your roads and railroads before anything else. If one were to take a cursory look at Europe's map today, what one would see would not differ much from a nice dish of Italian spaghetti. Roads and railroads, together with European economic integration, free trade, and the abolition of national borders, opened up the market for port services. Before people knew it, any Asian cargo could in principle reach any European destination, passing through any gateway port around Europe. Port demand was no longer captive but *stochastic*, and ports started to compete fiercely for custom, particularly for *transshipment*—i.e., other peoples'—cargo.

Port Reforms

Around the world, the port industry has invested heavily in order to cope with the intensifying competition. Modern container terminals—and corresponding cargo-handling equipment—have been built and new, more efficient, organizational forms (including privatization) have been adopted in an effort to speed up port operations. Private interest manifested in *dedicated container terminals* (Haralambides et al., 2002), operated/owned by the carriers themselves, and in the emergence of private terminal operators with extensive terminal investment portfolios around the world (Some notable ones at the time of writing are China Shipping Ports; Hutchison Port Holdings (Hong Kong); PSA International (Singapore); APM Terminals (Denmark)). Moreover, operational practices have been streamlined; the element of uncertainty in cargo flows largely removed; forward planning has been facilitated; port labor regularized; and customs procedures simplified. These developments took place under the firm understanding of governments and local authorities that ports, now, constitute the most important link (node) in the overall door-to-door supply chain and thus inefficiencies (bottlenecks) in the port sector can easily whither all benefits derived from economies of scale in liner shipping and in global supply chain management.

To modernize and face competition, ports have often invested far ahead of demand. A combination of factors can explain this. Excess port capacity, over and above national demand requirements, is often created in the belief of the infamous economic law of Jean-Baptiste Say according to which “supply creates its own demand.” In other words, once the port is there, the customer is bound to arrive. Unfortunately, this is not always so, particularly in cases where those who run ports have no competence in modern port marketing. Next, adequate berthing capacity is necessary in order to turn ships around as quickly as possible. Otherwise, a “footloose” container, with no loyalty to any port, might move easily to an adjacent competitor. Queuing theory easily shows that once a port reaches 70% capacity utilization, congestion starts to set in and this is something no modern port can afford. In this light, excess port capacity should be seen as an “operational necessity,” or cost, rather than as inefficiency or a waste of scarce resources. Carriers, having the upper hand as a result of their higher negotiating power (conferences, alliances, consortia) are able to play one port against another, forcing them to invest excessively in infrastructure. Finally, managerial egos, easy and cheap public finance, and port managers' heartburning desire to leave their footprint in history would all play a role, together with *economies of scale* in port construction: apparently, it is much cheaper to build 2 km of quay-wall rather than one.

Financing and Pricing of Port Infrastructure

Investment in container terminals, however, is not without risks, particularly if the investment aims at capturing container transshipment traffic which, as just said, is “footloose.” The situation is not helped much by the increasing competition among

neighboring ports, aimed at “stealing” transshipment traffic from each other. To do this, ports usually discriminate against (captive) domestic cargo in their pricing policies, while underpricing (footloose) transshipment cargo. (Under-pricing here should be taken to mean the charging of port dues and concession fees below the opportunity cost of port land.) This is particularly worrying in publicly funded port investments. Clearly, there is a need for public policy intervention, at least in the Europe Union, which needs to harmonize public spending among its member states, as well as to ensure free and fair competition among its ports. Solutions to this problem include transparency in port accounts; a common glossary of port finance terms; and pricing aiming at cost recovery (Haralambides, 2002).

Moreover, the automated nature of container terminals creates comparatively limited employment and this has been an additional reason governments are often seen reluctant to fund transshipment facilities whose benefits are not localized but diffused from the land of (Asian) origin to the country of (European) destination of the goods. In the form of a witticism, it is often said in the Netherlands that “the Port of Rotterdam is Germany’s biggest port.” Also, arguments are not rare in Germany regarding the usefulness of spending taxpayer money to maintain motorway A1: a north-south, motorway which facilitates Asian exports to reach European countries, rather than having the regional and developmental impacts infrastructure is supposed to have.

In comparison, the port of Antwerp, as a result of its multipurpose, more labor-intensive, character, creates four times more value added per square meter of port land than Rotterdam, the latter port being a highly automated and labor-saving. Thus, the Belgian taxpayer is much happier to pay for port development than his Dutch counterpart, who has often questioned the social utility of developing more port capacity at Rotterdam.

Exceptions to the above do of course exist, and Rotterdam is a good one: the port’s value added is not created simply by cargo-handling, storage and concession leases, but by its *port cluster*, encompassing 50% of Europe’s Asian and North American European Distribution Centers (EDC), in a city 50% of whose inhabitants are holders of a foreign passport, just because of the port. Unfortunately, not all ports can realistically aspire to such an enviable situation, developed not today but over a period of 70 years of hard work.

The Impact of Containerization on Port Planning, Development, and Operations

Containerization

It is many times said that *containerization* has revolutionized the transport and port industries. Such an emphatic characterization could be quite acceptable if one considers the enormous impact this originally purely technical solution in cargo-handling methods has had on the design and sizes of general cargo ships; the lay-out, equipment, development, operations and employment in ports; on inland transport requirements; land use; human skills; and shippers’ perceptions regarding the functioning of the overall supply chain.

The innovation entailed in the concept of containerization is credited to Malcolm Mclean: an American trucker who thought of separating the tractor from the trailer part of his trucks, standardizing (unitizing) the latter (trailer) so as to be able to be transported—with its contents intact—by various transport means, handled at ports by standardized cargo-handling equipment (quay cranes), and stacked uniformly one on top of the other, both in ships and at terminals. The container, or the maritime container, as it is often called, is a fairly robust and sturdy structure, manufactured at very high standards, intended to withstand the harshest of conditions, such as those often prevailing on the high seas. Containers are waterproof, vandal-proof, and adequately ventilated, to avoid possible accumulation of condensation, and, if treated well, they could give their owner many years of problem-free service (the average economic life of a container is 15 years). There are many types of containers (high cube, flat rack, open side, open top, tank, reefer (refrigerated), etc.), depending on the intended use.

Containerization’s Impact on Ports

General cargo goods are now increasingly carried in containers of standardized dimensions; most common is the $8 \times 8 \times 20$ feet container known as TEU—Twenty (feet) Equivalent Unit—, although containers of double this size (FEU—40 feet) are increasing in importance. Perhaps one of the most important effects of containerization is that, now, containers can be packed (stuffed) and unpacked (stripped) away from the busy waterfront, either at the premises of the exporter (consignor) and/or the importer (consignee), or at Inland Container Depots (ICD), warehouses, and distribution centers (dry ports).

By-passing the waterfront in the stuffing and stripping of containers, and thus having them ready in port to be handled by automated equipment, has increased immensely the punctuality, predictability and reliability of cargo movements and transport systems, enabling manufacturers and traders to reduce high inventory costs through the adoption of flexible Just-in-Time and Make-to-Order production technologies. Inter alia, such technologies have helped manufacturers to cope with the vagaries and unpredictability of the business cycle and plan business development in a more cost effective way. Indisputably, containerization has been the kindle wood under global logistics and supply chain management. And more: The concept of logistics does not stop at cargo systems, but it permeates every aspect of our everyday lives. For instance, in a reliable transport system, I know precisely what time I need to leave home to make it to the airport. But if taxis are frequently on strike; rail under continuous maintenance; or security controls at airport a mess, I need to leave home an hour earlier. And this hour is “my” inventory cost.

Figure 5 Cargo-handling before and after containerization.

Containerization and Labor Productivity

Containerization has had a number of significant advantages over the conventional, labor-intensive methods of handling general cargo. Apart from the remarkable improvements in port safety and the limitation of pilferage, damages and cargo claims, the system's major breakthroughs—particularly in the United States where it was first introduced—were in cutting down on expensive and often abusively organized labor, as well as reducing ship turnaround times.

Fig. 5 shows cargo-handling operations before and after containerization. Labor productivity in the earlier days (left side of Fig. 5) was roughly 1 ton per man-hour; with containerization (right part of Fig. 5), this went up hundredfold. In the first case, a docker would climb up the gangway 10 times an hour, with a sack of rice on his shoulder. In the second, a crane-driver would load 20 containers of rice onboard the containership, comfortably seated and handling a “joystick” from the cubicle of a ship-to-shore gantry-crane, or from the terminal office, or even from his home! The first docker would be paid peanuts (if he was lucky) while the second has a salary every worker in the world would envy today.

Containerization's Impact on Maximum Containership Sizes

The dramatic improvements in cargo-handling operations, brought about by the introduction of containerization, have enabled general cargo ships to spend hours or days now in ports, rather than weeks or months that was customary before. The reduction of port time, and the corresponding increase in time at sea, have eventually led to the substitution of the previous multipurpose general cargo ships by specialized high-speed container vessels of substantially (and ever increasing) larger dimensions (Fig. 6) which can take advantage of the *economies of scale* afforded by the shorter port turnaround times. Port efficiency and productivity have thus been the main drivers behind the increase in containership sizes, particularly since 1988 when American President Lines introduced the postpanamax vessels (Fig. 6). Up to that year, the maximum size of containerships (and of course of other types of vessels) was determined by the width of the Miraflores locks of the Panama Canal and it had remained constant, at around 4500 TEU, for almost a decade.

Mega-Ships and Diseconomies of Scale in Port

Undoubtedly, *Economies of Scale* in shipping have led to cargo consolidation, as well as to storage and distribution requirements, and thus to the emergence of global hubs and global logistics as we know them. There are, however, limits to the growth in ship sizes and these depend on freight demand; port capacity and technology; land infrastructure; other logistical costs; the future of global shipping alliances; and the attractiveness and future of the hub-and-spoke system in container transportation.

Gigantism in container shipping (Haralambides, 2019) has been the combined result of competition and concentration in this industry, as well as of shipbuilding technology which has made possible the construction of 400-m long ships, able to carry in excess of 22,000 containers (at the time of writing). The objective of the mega-ship trend has been to enjoy *economies of scale* leading to reductions in unit costs. Up to a point, this has been an economically legitimate objective, until diseconomies of scale start to set in, particularly in ports, that is, the place where start the “supply chain diseconomies of scale” of larger ships, including their impact on shippers' inventory costs.

To enjoy economies of scale and low costs, the ship needs to sail full and spend as little time in port as possible. In other words, carriers often require from the port that the ship be turned around at a given fixed time, for example, within 48 h, irrespective of its size. For most ports, this is a challenge. Whenever this is the case, it can be shown (Haralambides, 2017) that it costs more to handle a container arriving on a large ship than one arriving on a smaller one. In other words, port time per TEU is an increasing function of ship size, and this is a distinct “port diseconomy of scale” (Fig. 7).

		Nominal TEU tdw	LOA m	Breadth m	Depth m	Draft m
MSC GÜLSÜN 6 units in series from July 2019		22,960 teu 228,149 tdw	399.9	61.5	33.2	16.5

It is not so difficult to understand why: As crane productivity cannot be stretched much beyond 30 moves/h (it actually declines after a certain *crane density*), the only way to serve a larger ship in the same time (48 h) is by adding more and bigger (in terms of *air draft* and *outreach*) cranes. However, increasing crane density—that is, the number of cranes per 300 m of quay length—reduces crane productivity, among others nullifying the advantages of having bigger hatches.

Fig. 7 deserves a few more words. The downward-sloping blue line describes the economies of scale in shipping. One would observe that, after a certain ship size, the line becomes flatter, that is, economies of scale are actually lost. The red lines expresses diseconomies in port as a function of ship size. At smaller sizes, one would observe, the line is fairly flat, meaning that the time required to handle a ship increases linearly to its size. After a certain size, however, the line starts sloping upwards, meaning, as said already above, that it takes more time to handle a container arriving on a bigger ship. The u-shaped black line above is the sum of the

Figure 7 Optimum containership size and diseconomies in port.

other two lines, representing the “usual” compromise between two opposite developments: If one were to take into account, together with the benefits of bigger ships, the costs these impose on ports, the optimum ship size should be much smaller. In practice, port costs that should be taken into account go beyond cargo-handling time and into the significant infrastructure investment costs ports are obliged to undertake in their “anxiety” to attract the increasingly bigger ships from their competitors. At some point in time, the taxpayer will have something to say on this, particularly in view of the limited impacts of highly automated terminal operations.

Big ships impose substantial demands on port capacity, without however paying commensurately for this demand. For instance, when it comes to berth utilization, whereas before we could accommodate three Panamax vessels (i.e., three berths) along 1 km of quay-wall, today we can host there only two mega-vessels of the latest generation (about 400 m long each). Berth utilization obviously goes down and so does the utilization of Ship-to-Shore (StS) cranes, for bigger ships mean lower call frequency. A port manager responsible for his bottom line might have a problem in explaining this to his shareholders or supervisory board, unless carriers were bringing more traffic to the port with their larger vessels. But this does not happen either. As it can be shown (Haralambides, 2019), *call size*—the amount of containers a ship drops at a certain port out of the total number of containers it carries in its itinerary—is only moderately correlated with vessel size.

Finally, one needs fewer bigger ships, and fewer port calls, to serve a given amount of yearly demand. Thus, *connectivity* goes down and, with it, the contribution of shipping to trade and development. Here too, berth and crane utilization decline and this impacts on the capital costs of the port and of the terminal operator. In addition, a reduction in the frequency of carrier itineraries (i.e., number of services), caused also by slow-steaming, impacts the inventory costs of traders, thus defying the very principles of supply-chain optimization; and this is a clear *diseconomy* along the supply chain.

Hub and Spoke Systems

The capital intensity of mega-ships obliges them to limit their ports of call at each end of the voyage to just a few *hub ports* or load centers such as Shanghai, Singapore, Hong Kong, Rotterdam, or Hamburg. Here, thousands of containers are consolidated each day for export, and import containers are distributed with smaller vessels (feeder), rail, road, or river barge, to regional and local ports and final destinations. Complex *hub-and-spoke networks* have thus evolved whose logistical fine-tuning and optimization bears directly on consumer pockets.

Such a hub-and-spoke network is depicted in the infographic of Fig. 8. Ports 1 and 3 are both gateway and transshipment hubs in continents A and B, respectively, while Port 2 is a pure transshipment hub along the way. Ports 4 and 5 are other ports of call in the proximity of the two hubs, while ports 6–12 are regional facilities.

A pure transshipment hub such as Port 2 is a facility with comparatively limited domestic traffic. Examples are Damietta, Malta, Singapore, Gioia Tauro, Colombo, and Kingston. Without some captive (domestic) cargo base, transshipment hubs are risky investments due to the “footloose” nature of the container. Two roles need to be present in a successful hub like Hamburg or Rotterdam: A “gateway” role (i.e., serving domestic cargo) and a transshipment role, in fairly balanced proportions. Also, regardless of the typology of a hub, i.e., foreland consolidation hub like Singapore or hinterland distribution hub like Rotterdam, two elements

Figure 8 Hub and spoke systems and feeder networks.

(I have decided to leave this figure as an infographic for the benefit of hundreds of colleagues around the world who use it in their course materials).

should be present for successful operations: *centrality* (to main consumer markets) and *connectivity* (in terms of frequency and number of shipping companies calling at the port).

Cargo distributed from a hub port is also *feedered* on smaller ships to regional ports. This is done in two ways: shuttle feeder routes or cyclic routes. Shuttle feeder routes are ideal between ports with relatively high freight demand. They offer short transit times, and employ more and smaller feeders. Cyclic routes instead are more appropriate for feeder ports with lower freight demand. Cyclic routes benefit from the economies of scale of the bigger feeders, but imply longer distances and transit times. There are two types of feeder companies: Dedicated feeders (belonging to major mainline carriers like Maersk and Cosco), who also operate as common carriers, that is accepting cargo by third parties, and "common carriers." The global feeder market is estimated to 60 million TEU/year (Polat et al., 2014).

Summary and Conclusions

A bicycle manufactured in Wuhan (China) can reach Vienna (Austria) in 147 different ways; which one is the best? During the past 20 years, ports have come to realize that it is actually supply chains themselves that compete while they, ports, are important, not to say crucial, *nodes* along those supply chains. Ports have thus also realized that inefficiencies of whatever nature in their operations can jeopardize the efficiency of the overall supply chain.

At the same time, the development of land infrastructure around the world has expanded the catchment areas (hinterlands) of ports and has thus intensified competition amongst them.

These trends, amidst the container revolution, have forced ports to modernize from the slow, expensive, inefficient and bureaucratic public facilities of the past, to modern enterprising entities, increasingly operating under principles of commercial management.

Port infrastructure has thus become not only the pivotal facilitator of international trade, but also a lucrative asset for private investment, as evidenced by the many *global terminal operators*, developing impressive port terminal portfolios around the world.

Infrastructure investments around the world will amount to trillions of dollars in the course of the present century. The financing of infrastructure is increasingly undertaken with heightened attention, in view the mounting public debt of countries, and of the property of infrastructure to require long gestation periods, while the servicing of its debt cannot wait. In this light, ports and port terminals could be seen as "success stories" in the financing and development of infrastructure, setting a most useful example for others to follow.

Biography

Since 1992, Hercules Haralambides is Professor in Maritime Economics and Logistics, having taught at eight universities (and in six different countries), most prominent of which being Erasmus University Rotterdam and National University of Singapore. Currently he is Distinguished Chair Professor at Dalian Maritime University (China) and Adjunct Professor at Texas A&M University (USA). Hercules is the founder of the Erasmus Center for Maritime Economics and Logistics (MEL) (<https://www.maritimeeconomics.com>) and also the founding Editor-in-Chief of the quarterly journal Maritime Economics & Logistics (MEL), published by Palgrave-Macmillan (<https://www.palgrave.com/41278>). He has written and published over 300 scientific papers, books, reports, and articles in the wider area of ports, maritime transport and logistics and has consulted governments, international organizations and private companies all over the world including, for a series of years, the European Commission. In the period 2011–5 Professor Haralambides was President of the Italian port of Brindisi and at the end of that period (2015) he established “Haralambides & Associates”: a global maritime think-tank engaged in executive education and strategic policy analysis. In 2008, Professor Haralambides was decorated with the Golden Cross of the Order of the Phoenix, by the President of the Greek Republic.

Introduction

This paper is organized as follows: The first section presents a historical perspective of the main changes developed in port management models as a result of the transformations of the shipping industry since the late 19th century. Then, we present the main port management models observing their main characteristics as well as their administrative and institutional structure. The last section includes a general approach to the governance structure in ports and its decisive influence on the insertion of ports in global economic networks.

A Historical Overview of Port Management Evolution before the 1980 Decade

Before the arrival and development of steamship during the second half of the 19th century, port management structure was relatively limited to a number of civil servants engaged on the collection of taxes, health inspection, and other military issues. The low-intensity schemes of maritime traffics and the scarce development of port infrastructures during the preindustrial age did not demand complex administrative structures for the most of seaports in spite of the existence of specific major trade centers where administrative organization was relatively more complex. Nevertheless, the rapid expansion of steamship throughout the late 19th century fostered major changes at both, institutional and entrepreneurial levels (Harlaftis et al., 2012). Advances on maritime shipping developed during the industrial revolution promoted the sustained international trade growth where seaports had played a key role as nodes for the spread of economic globalization.

Moreover, maritime networks were reinforced in a global scale and ports rapidly received the massive attention of policy makers as well as national merchant fleets expanded and international trade flourished. Thus, seaports were conceived as essential tools for the wealth of the nations and reforms should be made in order to enlarge commercial traffics and connect them to economic progressive regions. However, reforms would include institutional and management issues. The increased complexity of port communities and the variety of new activities born in the heat of globalization demanded administrative reforms. Hence, major port reforms (both at the institutional and physical levels) were led—in overall terms—by the state as a consolidation of public liberal reforms developed throughout the 19th century.

Since the 1880, in most of industrialized countries, the government assumed the task to modernize ports and waterways as a mechanism to foster the economic performance of their respective countries. Public reforms on port management were then led by the central government to introduce policies of relative coordination between ports into the same country. This coordination was building on similar taxes and more broadly on common regulatory frameworks in terms of international trade in order to avoid interport competitiveness. Reinforcing port activity required a trained staff heavily composed by engineers and marine officers. The administrative staffs also included economists and lawyers whom role was to create an appropriate environment for the investment of private port companies and the attraction of maritime traffics.

On the other hand, there were port managements models built on historical paths such as them dependent on public local bodies where interport competitiveness was encouraged even into the same country. In addition to that, private actors operated private port

such as ore or bulk-trade terminals as the result of public concessions made by the public institutions throughout the 19th century. Through the establishment of agreements with the public institutions, private operators exploited the port terminal and contributed with tax-collection, annual fees, and other revenues to the public expenditures.

In overall terms, port management structures since the late 19th century up to the 1980 decade were characterized by slow developments and the progressive adoption of managerial structures dominated by the weight of the state and public bodies in their management and decision making.

Nevertheless, considering port management evolution in the long run, it could be argued that the nature and specificities of the different models were deeply affected by historical, economic, and political endowments. Impressive transformations on informatics, the renaissance of liberal policies, and the further effects of the second wave of globalization since the 1980 decade fostered structural changes on the way how port management was conceived (Kaukianen, 2014). Since that decade, port authorities emerged as local-regional key actors. These institutions received increased competences from the national governments and state agencies in terms of planning and economic strategy. Those authorities tended to collaborate with the private sector in a process known as “devolution” that represented the increased economic and political importance of regions.

Main Port Management Models

The trade globalization implies a heavy integration between supply chains and productive structures being all of them heavily dependent on the efficiency of the transport system. The ports, as part of both the supply chains and the transport system, play an important role in the integration of the different transport modes into the supply chain structures. Consequently, port management turns out to be a crucial factor in the trade globalization. It involves the performance of several agents jointly operating at different levels (local, regional, transregional, and global) and additionally, the participation and interaction in a broad sense of public and private partners: port authorities, port users and associations, international institutions, global investors, and so on. The contemporary port management theoretical frame involves a number of formal and informal institutions and the common recognition of rules and managerial structures ultimately oriented to foster traffic growth, in a free trade framework promoting socioeconomic welfare and environmental protection. Interaction between private and public actors requires a comprehensive legal structure compatible with global trade networks. The way the public and private actors are intertwined within the ports, defines on the other hand the different management models. All of them, involves the use of strong analytical tools to help their implementation at the different levels of the ports structure extending their scope from the financial aspects (investments, profits, assets, cash, solvency) to operations (ship handling, cargo handling, service provision, environment protection). These elements also include all the different aspects of a modern port day to day management, from human resources to market orientation.

Broadly speaking, port management includes all the aspects of the day-to-day modern port performance but one of them has come to be especially relevant: port governance. Involving most of the components of port management, port governance models are focused in the institutional aspects of the port performance defining the institutional framework that relates and intertwine all the stakeholders involved in the port life. Given the crucial role of the port authority (PA) in the modern port life, the governance of the ports can be approached in two different ways: port governance and PA governance. Port governance regulates the interactions between the different port services and companies, how they are managed and how they interact with the port (World Bank, 2007). PA governance on the other hand is referred to the way that the PA is internally managed and how it interacts with the public administration, the port companies, and the rest of port stakeholders (Caldeirinha et al., 2018). Because of the extended implementation of the devolution concept, the port authorities play more and more the role of a business company. Acting with a very high degree of autonomy, they are managed as any other corporation involving not only day-to-day administration but strategical issues as regional development, supply chain insertion, port–city interactions, and maritime and land connectivity. As in any corporation, is governance at the end what defines both the internal relationships of the PAs and the external interconnection with their stakeholders.

Port Structure

Since there are many aspects involved, it is useful to divide seaport activities between: (1) infrastructure, (2) services provided by the port, which require the use of the former, and (3) coordination between the different activities performed at ports. The main characteristics of these three elements are analyzed below (Fig. 1).

Therefore, there are many different activities being performed simultaneously within the limited space of port areas, with ships constantly entering, being serviced and exiting. Therefore, there is a need for an agent to act as a coordinator to ensure the proper use of common facilities, and to take care of safety and the general design of port facilities. In most seaports, this function is played by an organization called the *port authority*. These are generally public institutions, where local interests are represented, but this configuration is not unique, and it is possible to find examples of purely private port authorities (Trujillo and Nombela, 2000). There are several organizational modes for seaports, depending on the role that port authorities assume. These are usually labeled as *landlord port*, *tool port* and *services port* (public or private).

Figure 1 Port structure.

Port Management Models

Port management models evolved hand in hand with the 1970s port reform processes that gained momentum in the late 1980s with the public-sector reform in the United Kingdom followed in the 1990s all over the world. The British experience had a great impact on the consequent reform processes since it meant a radical change in the way the ports were managed. Part of the British port system was fully privatized including land property, complete absence of regulatory bodies and the deregulation of port labor market. In the subsequent port reform processes boarded from the 1990s until now all over the world, this approach has been considered radical in excess, not being extensively followed in its wholeness (Brooks and Pallis, 2011). In 2005, the World Bank in a highly cited work, set up the basis of the modern port governance models in its World Bank Port Reform Tool Kit (WBPRTK) in an attempt to systematize port governance models. Widely used all over the world especially as a guide for port reforms in the developing countries, this tool kit highlights the role played for the PA as a crucial actor in the management and governance of the ports, classifying the ports according to this role in public service ports, tool ports, landlord, and private service ports. Defining in this way the role of the PA, this classification gives a clear picture of the balance of functions and responsibilities between the private and the public sectors (Trujillo and Nombela, 2000).

There is an ample variety of port governance models what makes very difficult a detailed analysis of all of them. It is possible however to find common characteristics—variables—in order to identify the different tendencies followed around the world in the port reform processes conducting to the main port governance models. Thus, in Europe we can find three main tendencies defining the corresponding models: the Hanseatic model, mainly based in governance performed by local administrations, the Latin model with a more centralistic approach and the Anglo-Saxon model based in a completely independent management most of the time in private hands (Suykens and Van De Voorde, 1998).

Many others types and subtypes of governance models are applied all over the world, depending on the political environment, the size of the ports, their integration in the supply chains, the public administration traditions, and in general, any aspect of the port management influenced by the governments, local and PA, and the rest of stakeholders involved in the port life. Given the PA preeminence, the activities, performed by these institutions, constitute an important variable of port governance. It must be remarked that the already mentioned World Bank classification of the ports—according to the PA role—as public service ports, landlord ports, tool ports, or private service ports is not rigid, presenting an institutional plasticity and normative adaptation to the local characteristics of each region, country, or even ports. It is also interesting to note that any of these models can be considered as potentially more efficient than the others.

Public Service Ports

Public service port management models are mainly defined by the predominance of the public sphere on the governance structures. In these ports, the port authority is the main actor, performing all the services and owning the whole infrastructure. Being normally part of a higher-level public institution as a ministry or government department, the port authority is responsible for the construction, management, and operation of the whole port's infrastructure. Thus, is a public institution who supervises, guides, coordinates, and control port activities. Consequently, with all these, port funding is almost entirely dependent on public finances. However, even under full-public port management models, the private sector also could benefit from concessions and specific agreements for the provision of services. More and more, these types of ports enhance the participation of private actors providing these services through cooperative entrepreneurship strategies, approaching these ports to the tool port model.

Tool Ports

This kind of model is an intermediate step between the public service port and the landlord model. As in the service ports, the port authority is still preeminent, owning the infrastructure and performing most of the services. Cargo operations, however, are performed by private companies operating in terminals and docks owned by the port who owns most of the time the handling equipment too. As a transitional model, the tool ports are of especial interest for developing countries pursuing the improvement of the port system efficiency but unable to transfer the total control of the port operations to private hands either for political reasons, market deficiencies, or the lack of administrative resources enough as to enhance and control an extensive devolution process. It often happens in addition that the size of the ports in these countries is not large enough to justify a private company investing in a cargo terminal or any similar infrastructure, so it is the public administration that must face the investment.

Landlord Port

Landlord ports are the clearest exponent of the devolution process initiated in the 1980s to transfer services in ports from the public sector to private corporations. As an evolution of the tool port toward the fully privatized port, it is an intermediate solution that protecting the public interest. It enhances the efficiency and productivity of the ports, being nowadays the predominant model in the developed countries. However, we could remark some exceptions as the United Kingdom that embraced the fully private model in some of its ports after the reform of the 1980s.

Forced by the challenges of the globalization, public powers looked for a model that evolving from public ownership and control to public–private partnership. These governance models were able to avoid the current inefficiencies derived from heavy bureaucracy, lack of market orientation, political interference, lack of financial capacity to board the huge investments associated to the industry, and even the distortive effect of the trade unions power, traditionally very strong in the ports all over the world.

The model involved strong devolution processes transferring most of the services and responsibilities from public institutions to private entities. Under this collaborative schedule, the public institutions remain as the owner and provider of the major infrastructures, transferring to private investors the economic exploitation of ports services, what results most of the time, in the concession and transference of public dominion to private agents over port infrastructures. Through this transference, the public administration holds the property of the land leasing it to a private corporation—normally via a concession agreement—for a determined period. The lessee acquires the commitment to make the necessary investments in restructure and equipment for the normal operation of the facilities. The amount to be invested is normally is specified in the concession agreement as well as the rent to be paid to the port authority—normally an amount per square meter leased—and any other charges and taxes of application. There is an ample variety of concession agreements but most of the time, the lessee compromises a minimum volume of traffic to be operated on the facility on an annual base and during the whole period of the leasing contract. Discounts and exemptions are normally applied on a progressive scale by the port authority if this minimum volume is exceeded. For the case that the compromised investment during the whole leasing period is exceeded, is a common practice too to contemplate in the concession agreement, discounts, exemptions, or even an extension the leasing period according to the exceeded investment.

In what respect to the port services (anchoring, port pilotage, berth occupation, etc.), it is normally the port authority who determines the maximum tariffs for them, as well as the different taxes and the necessary basic regulations such as environmental or labor and safety protection policies. Most of the time, the PAs are at the same time the economic regulator that warrants the fulfillment of the economic conditions of the concession agreements and services licenses. This scheme present regulatory problems since the proximity of the PAs to the operators can lead to the capture of the regulator.

Moreover, the role the port authority also includes the political and economic promotion of the port as well as negotiations with public–private national and international partners fostering and promoting port competitiveness in order to attract seaborne traffics and investments from the private sector. The public sphere is also responsible for infrastructure planning and investing, funding expansion and improvement works of the basic infrastructure.

Private Service Ports

This management model is the extreme case of the application of the devolution concept. In fact, implies the full privatization of the port's infrastructure conditioned to the maintenance of their original function: to attend and handle the maritime traffic. It implies the full-private ownership of port infrastructures as well as full-private management of the services. Consequently, are private investors after obtaining of the corresponding permissions, who entirely build, exploit, and manage the port infrastructures. This model is based on a full autonomy in terms of funding and planning strategy. Private stakeholders entirely face the risks and benefits of their investments. Hence, under this administrative scheme, competitiveness and efficiency are privileged. Thus, the port is conceived as an integrate private company providing the complete range of services. The role of the state is quite limited, maintaining in any case the regulatory functions under the national legal framework in issues like environmental regulation, labor conditions, maritime safety, etc. In some cases, public entities can be integrated as shareholders of the port corporation in to keep a certain degree of influence in the port policies, orientating them to promote and safeguard the public interest

Ports Insertion into the Global Networks: Governance Implications

The integration of productive processes in the global supply chains has forced the ports—as nodes of interchange—to integrate themselves into these chains. This integration is carried out through the port operators that suffer a double direction integrative process: upstream, into the supply chains they serve and downstream, into the ports in which they operate. This process has also a double character: operational upward and territorial downward.

Operationally, the port operators are integrated into the systems and procedures of the supply chain, including every step from the production process to the final distribution of the product. In short, production, transportation, administrative processes, and information flow and all this, in a continuous process incorporating at every moment. Thus, the technological improvements that are taking place in each one of the links of the chain affected the process as a whole.

This operational integration is what explains the position taken by many of the global shipping groups in the port terminals business through processes of vertical integration that allow the insertion of handling operations in the maritime transport link of the supply chains and consequently, in the whole operation of them.

Territorially on the other hand, the port operators are integrated into the port spaces, immersing themselves into the administrative, legal, and operational systems of each port. This territorial integration, would explain to a large extent the processes of horizontal integration that have led to the creation of port operators participated by shipping alliances that, through the application of economies of scale, can extend their penetration into ports on a global scale, conducting in many cases to situations of monopoly in some ports.

From the point of view of both the public interest and port governance, the previous scenario poses a double problem. On one hand, the strong concentration in the sector of terminal operators gives them a very high negotiating capacity against the PAs, that in many cases are also the economic regulators of this industry. This capacity is reflected not only in terms of negotiating administrative concessions contracts, but demanding and imposing special working conditions, operational priority or preferment tariff rates, what can lead in many ports to situations of predominance even with the capture in some cases of the regulator. The special characteristics of the container traffic increases this negotiation capacity in that, the port operator—most of the time part of a shipping group—not only provides both, transport and handling capacity, but the possibility of increasing the volume of the port operations bringing to the port transshipment traffic. On the other hand, the position of the APs is strongly conditioned by the fact that if they invest public money in new infrastructures, such infrastructures must be used exclusively for the purpose that is designed, what requires a specialized operator willing to invest in the auxiliary infrastructure and running the risk of the business during the concession period.

The result of all this is a balance situation in which the PA has already made the investment and needs to use it and the operator on the other hand, controls the traffic and has the know-how but needs the physical infrastructure. This balance situation has its most clear manifestation in the process of granting concessions, where the bargaining power of each of the parties is revealed. It should be borne in mind that the strong concentration of port operators has given rise to large groups of global terminal operators (GTOs), what increases substantially their bargaining power. On the other hand, and especially in the landlord-type ports where the devolution concept is widely extended, the PAs have no other option that negotiation with the operators in order to provide the port with efficient infrastructures.

The governance implications of the above are relevant but suffice to say that the PAs have the normative and legal capacity to favor what it would come to constitute the best policy of safeguarding the public interest: the stimulation of the intraport competition. The AP is who has the capacity to favor the reduction of entry barriers that impede the access of new actors to the port activity, acting on the three barriers that traditionally are considered relevant in the port activity: economic, regulatory, and positional barriers. The economic entry barriers are derived from the fact that established operators can compete with lower costs, mainly for three reasons: better location in the port area, lower operating costs due to economies of scale, and benefits derived from cumulative public investment (De Langen and Pallis, 2007). It is the case in many ports that an already established operator -especially if it has reached an important volume of operations—opts to a terminal concession tender from a position of clear advantage. This predominant position would be also fostered both by its location and by its operating costs—product of the magnitude of its turnover-, benefiting also from accumulated public investment (as land connections to the terminal that it is already operating).

Regulatory and positional barriers to entry are less important from the point of view of intraport competition, but they are interested from the point of view of interport competition. Thus, regulatory barriers may in general be the same for all operators in a particular port, but between competing ports those barriers can be different. The same would apply to positional barriers that are derived from the fact that land in ports is always limited, which would affect all operators in a port, but could favor the establishment of new players in nearby competing ports with available land.

It can be concluded that the devolution processes lived in the ports all over the world in the last decades give a great prominence to the GTOs that have gained a significant bargaining power along the years. In order to cope with this situation, keeping the advantages of the landlord scheme in terms of efficiency, investment capacity, and operational flexibility, protecting at the same time the public interest, the PAs have the normative and legal capacity to promote intraport competition what seems to be the best way to balance this situation.

Summary and Conclusion

This article has pointed out the main differences between the existing port governance models. Each of these models also offers other institutional specificities as a result of adaptation to the local environment. Therefore, the level of efficiency of each of these management models must be observed in their context, both institutional, but also economic and social. Finally, this article has remarked the relevance of port management models in the context of the global supply chain. Ports act as essential nodes for the operation of international commercial exchanges, adapting their administrative structures to these global and interconnected dynamics.

Introduction

As argued by [Goss \(1990\)](#), the economic function of seaports is to benefit producers and consumers from the trade that passes through them. This implies maximizing consumers' and producers' surpluses, which in turn requires competitive conditions. However, the economic characteristics of ports may result in them enjoying considerable market power, and when this translates into anti-competitive practices, the sheer scale of port activity and the maritime industry more generally means that this will have serious adverse effects on end-users and the economy as a whole. This is underscored by the fact that maritime transport concentrates over 80% of the volume of international trade and over 70% of its value, making it essential for the global economy ([UNCTAD, 2018](#)). In cases where competition cannot be introduced to address this market failure through competition law, economic regulation will be required ([OECD, 2011](#)). Another form of market failure is the negative environmental externalities generated by port activity, and increasing concerns over climate change and the effects of pollution from port activity are driving moves toward more stringent environmental regulation. In this chapter on port regulation we will therefore discuss both economic and environmental regulation.

The chapter proceeds as follows. In the first section we define what ports are, their governance structure, and the economic characteristics that make them a candidate for regulation. The next section is dedicated to economic regulation, where we discuss price and access regulation and the use of port concessions as a regulatory tool. Environmental regulation is addressed in the following section and covers both internationally binding regulatory initiatives as well as voluntary initiatives that have been implemented by port management bodies to mitigate adverse environmental impacts. The last section concludes.

Ports: What are They and What are Their Economic Characteristics?

A discussion of port regulation requires a definition with some precision of what a port actually is. While this may seem obvious, a study by the [European Parliament \(1999\)](#) highlighted that the definition of "port" has changed considerably over time due to technological advances in maritime transport and the increasing role of maritime transport in national and world economies. Thus, the original meaning of port as a harbor, or refuge for ships, has given way to more comprehensive definitions that underline the role of ports in the transportation logistics chain and the different forms of management to which they are subject. This evolution is clearly described in the academic port literature, which classifies ports into five generations, with recent literature even referring to a sixth generation ([Kaliszewski, 2018](#); [UNCTAD, 2000](#)).

The [European Parliament \(1999\)](#) study also suggests a definition of ports as "commercial areas located beside water deep enough for sea-going vessels and having several or many port undertakings [and which] have special maritime as well as conventional road and rail infrastructure, and are supervised or administered by a public or private port authority." Thus, ports can be characterized as providing a wide range of different services using infrastructure, installations and mobile equipment by different agents. Moreover, ports can be owned and managed according to widely different models. The ownership and management structure of ports, the economic characteristics of individual port services and the possibility of whether competition can be realistically introduced will all determine the need for regulation and the type of regulation required. A useful working definition of economic regulation which we

use here is provided by [Decker \(2015\)](#), who defines it as “interventions that impact on the structure . . . or which attempt to guide or control the behavior of firms on terms of their decisions in respect of pricing, investment, quality, and coverage of service, as well as the terms on which access is provided to other firms, including competitors.”

Governance

Port management was traditionally characterized by a central public authority that was responsible for port development and that managed or operated the lion's share of port services. In recent decades, however, technological advances in maritime transport have increased pressure on ports to be able to provide service to larger and more specialized vessels and led to increased competition among ports to attract these vessels. Simultaneously, financial pressure on public sectors had led States to actively seek private sector involvement in the port sector in both the provision of services as well as investment in the construction of port infrastructures. This in turn has led to a need for regulation of private firms that provide port services in contexts of limited competition.

As summarized by the [World Bank \(2007\)](#), four main governance models of ports have emerged over time which the State can use to regulate the sector. These models are the public service port, the tool port, the landlord port, and the fully privatized port or private service port. The models differ with regard to characteristics: who provides the service (public, private, or mixed provision); orientation (local, regional, or global); ownership of infrastructure/port land and superstructure and equipment; and status of dock labor and management. As noted by [Ferrari et al. \(2015\)](#), the key difference between the models has to do with the possibility for private companies to manage port operations and be involved in port activities. Thus, public service ports and tool ports mainly focus on the realization of public interests, whereas at the other extreme, fully privatized ports—mainly found in the United Kingdom and New Zealand—focus exclusively on private (shareholder) interests. Unlike pure public ports, tool ports allow private operators to carry out activities within ports and in port terminals, although they cannot have their own infrastructure. According to the [World Bank \(2007\)](#), this model serves as a useful stepping stone to the landlord model, especially when the confidence of the private sector is not fully established and the investment risk is considered high. Finally, landlord ports aim to balance public (port authority) and private (port industry) interests. In this model, which is the dominant model in medium and large ports, the port authority acts as regulatory body and landlord, while private companies carry out port operations, especially cargo handling. While in principle there is no ideal model, [Monios \(2019\)](#) notes that there seems to be a tacit consensus in the literature on port governance that some version of the landlord model combining public ownership and private operation is the most desirable. [Monios \(2019\)](#) also notes that the terminal itself sits within its own chain of governance as it often forms part of a global portfolio of terminal operations and/or may be vertically integrated with shipping lines, such as APM and Maersk, that have a great deal of market power over individual ports. Hence, there are elements of both vertical (different levels in the transport chain, such as between carrier and terminal and sometimes hinterland transport) and horizontal (with other terminals) integration, that should be taken into account when it comes to port governance.

Economic Characteristics of Ports

Port infrastructure possesses a series of economic characteristics which have a bearing on competition in the sector and the possible need for public intervention and regulation ([OECD, 2011](#); [World Bank, 2007](#)). Among these are the fact that the demand for port services is derived (with the exception of passenger services) from the overall demand for transport between origin and destination. The choice of port will therefore depend on the generalized transportation cost, which comprises not only port service fees *per se* but also the cost of queueing and the transport costs from the port to the final destination of goods. The sensitivity of customers to changes in port services prices will therefore be smaller than their sensitivity to changes in generalized transport costs, raising the likelihood of excess pricing for port services. Another important characteristic is that port services may have few or no substitutes, which leads to low elasticities of demand with respect to prices and quality of service. On top of this, interport competition may not exist where there are captive hinterlands, comprising regions where a particular port may have a substantial advantage over other ports in terms of the generalized cost of transport to these regions. Ports on relatively small islands are a case in point.

Indivisibility of port infrastructure and superstructure, which require minimum sizes and which cannot easily be adjusted to the flow of traffic, is another characteristic and may lead to overcapacity or congestion in the port which can only be adapted to over relatively long periods of time and great cost. The long duration of the useful life of port infrastructure and its high cost generate uncertainty for investors in the sense that the returns from the large investments needed are generated over long time periods in a context of uncertainty with regard to demand for port services. Finally, ports generate externalities, both positive and negative. Positive externalities include spillover effects on local or regional development, whereas negative externalities include the contamination of local waters and beaches as well as air pollution and road congestion in port cities.

These characteristics of ports may lead to market power in some port services and lead to anticompetitive practices, including excessive pricing and refusal to grant access to port services. Also, if external costs are not internalized, ports may generate socially sub-optimal levels of contamination and pollution, leading to environmental degradation. These economic concerns over anti-competitive or “natural monopoly” behavior and the environmental concerns due to negative externalities have led to economic and environmental regulation in ports.

Economic Regulation

Standard microeconomic theory holds that competitive markets lead to Pareto-optimal allocation of resources. Market failures may hinder the achievement of competitive outcomes, and as we have seen, market power arising from natural monopolies may exist in ports, thereby providing a case for economic regulation.

However, even when competition cannot be introduced, care must be taken to ensure that regulation is in the public interest. The justification for public interest regulation is a market failure test based on three components (Church and Ware, 2000): (1) a determination of the existence and magnitude of inefficiencies if the market is not regulated; (2) determination of the feasibility of intervention to correct market inefficiencies; and (3) the benefits of regulation justify the costs associated with regulation, where these costs can be direct (costs of establishing a regulatory body, compliance costs for firms) or indirect (regulation-induced inefficiencies due to lack of incentives for firms to minimize costs).

If regulation is deemed feasible and realistic regulatory tools can be identified, care must be taken to prevent regulation from being overly restrictive or controlling in the sense that it should not deter private companies from providing services nor stifle their ability to introduce innovative and efficient practices. To avoid heavy-handedness in regulation, the World Bank (2007) suggest a series of guidelines to aid in the design of a successful economic regulatory policy for ports which fit in well with the market failure test components above. These guidelines include, for example, that governments should have a clear understanding of the competitive environment of the port sector and that regulatory decisions should be based on the risk of anticompetitive behavior.

The nature of the port service provided will determine the need for regulation. Following Trujillo and Tovar (2007), a distinction can be made between services requiring port infrastructure as a basic input (goods terminals, warehouses and storage facilities, etc.) and those that do not require infrastructure (pilotage, tugboats, etc.). When infrastructure is required, competition will be limited or nonexistent for the corresponding port services and regulation is needed to avoid abusive practices and inefficient behavior. When infrastructure is not required, competition can generally be introduced to the market provided the market is sufficiently large. If the market is small and the number of service providers should be limited, some sort of licensing scheme will generally have to be introduced.

The form of economic regulation (e.g., rate of return or price caps) and the circumstances where it applies should be clearly defined. Also, to avoid the risk of regulatory capture and potential conflict of interest between port operations regulation and competition policy, it is recommended that responsibility for these should be separated and assigned to two different entities. Finally, in terms of the costs of regulation, it is recognized that regulators will have to weigh the trade-offs between the need for information and the burden of the reporting requirements on the operators.

Price and Access Regulation

With the aim of eliminating impediments to the functioning of competitive markets or providing conditions which mimic competitive outcomes, economic regulation comes in two basic forms: price regulation and access regulation. The principal aims of price regulation in ports are to ensure that customers are not exploited through excessive prices and that the regulated firms receive a reasonable return on their investment. For example, the recent “EU Regulation 2017/352 of the European Parliament and of the Council establishing a framework for the provision of port services and common rules on the financial transparency of ports” states that the charges for services provided under public service obligation and services provided that are not exposed to effective competition (such as pilotage services) should be transparent, objective and non-discriminatory and “shall be proportionate to the cost of the service provided” (art. 12). The idea here is to avoid potential abuse of monopoly power, and elsewhere the regulation explicitly states that Member States are permitted “to regulate charges in order to avoid overcharging of port services in cases where the situation of the market in port services is such that effective competition cannot be achieved” (Recital 40, available at: <http://data.europa.eu/eli/reg/2017/352/oj>). Price regulation is usually appropriate when a port or port service is a natural monopoly. More generally, rate-of-return or price-cap methods may be used. Rate-of-return regulation involved setting prices in such a way that firms are permitted to earn a “fair” return on their capital investments. This has the advantage that firms will cover investment costs, reducing uncertainty over investment, but has the disadvantage that it provides little incentive for firms to reduce costs as they can pass increased costs on to customers. It also suffers from the well-known Averch–Johnson effect whereby firms overinvest in capital. Under price-cap regulation, on the other hand, maximum prices for services are set according to some variant of the RPI-X methodology, where the Retail Price Index (RPI) captures the inflation rate and ‘X’ is the ‘offset’ reflecting the firm’s expected efficiency improvements. Under this methodology, firms are permitted to keep cost savings until the review period finishes. The differences between the two methods of regulation have often been described in terms of the different incentives they provide. Thus, rate-of-return regulation is good at extracting excess rents from firms for customers, as prices are set to reflect the cost of service, but provides no incentives for firms to try to reduce their costs. In the terminology of Laffont and Tirole (1993), this scheme provides ‘low-powered incentives’. Price-caps do provide incentives for firms to reduce costs (‘high-powered incentives’) as they are the residual claimants for cost reductions, but this implies that excess rents are not transferred to customers, at least until the following review of the price cap.

Access regulation can be used to address problems of refusal of supply as well as reducing discriminatory practices when ports are capacity-constrained or where the port is vertically integrated with downstream interests. Access is commonly regulated under the “Essential Facilities Doctrine” under which a monopoly that owns a facility essential to competitors must provide reasonable access to this facility (Defilippi and Flor, 2008). Ports have been the principal vehicle for the development of the essential facilities doctrine

by the European Commission—see [OECD \(1996\)](#) for references to some legal cases illustrating the use of the doctrine. Regulators have different tools at their disposal to ensure access is granted, including transparency obligations, accounting separation obligations, publishing of access codes, and specification of equivalence standards governing the principle of nondiscrimination ([OECD, 2011](#)).

Port Concessions as a Regulatory Tool

Under the landlord model, concession agreements can be considered as a policy tool that enables Port Authorities to regulate the port without a direct involvement in the commercial activities of the port. In fact, for Europe it has been argued that port concessions appear to be the only common instrument to regulate the port market. Moreover, they appear to be the only effective means through which Port Authorities can achieve public service goals in the face of increasingly powerful shipping lines and port terminal operators ([Ferrari et al., 2015](#)).

Given their long duration and the existence of unknown future contingencies, concession contracts are problematic in the sense that they are incomplete, that is, the parties cannot express all contractual terms in detail. This in turn raises the issue of which party to the agreement has the right to make decisions over future contingencies and therefore enjoy greater bargaining power in possible renegotiation of terms. This may lead to opportunistic behavior, benefitting one or some of the parties at the expense of social welfare. In terms of concession agreements for port infrastructure, incompleteness of contracts can lead to inefficient or suboptimal investment, anticompetitive behavior and collusion, lack of transparency and clarity in the management of public–private partnerships, regulatory capture, vertical integration, and risk of exclusion of access ([Sánchez and Chauvet, 2019](#)). To ensure that infrastructural concession agreements align with social objectives, a solid institutional framework is therefore needed with efficient regulation and a strong competition policy. The issue is particularly problematic if an infrastructural services concession holder vertically integrates with one or more clients, as happens, for example, when a port terminal operator integrates with a shipping company or large logistics operator leading to the exclusion of other shipping lines from access to port services.

Environmental Regulation

Aside from greater economic efficiency and the attraction of private investment as goals of regulatory policy, there is an increasing emphasis on environmental sustainability in the port sector due to the negative environmental externalities produced by ports as well as the effects of climate change on ports through phenomena such as, for example, rising sea levels. Seaports, as major centers of economic activity that are usually located near highly populated areas, generate significant air pollution for coastal areas and port cities. As generators of greenhouse gas emissions, they also contribute to global warming. It should be noted that the legal framework for measures to combat greenhouse gas emissions extends beyond the maritime industry and any particular geographical area, with relevant international regulatory developments including the implementation of the 2030 Agenda for Sustainable Development and the Paris Agreement under the United Nations Framework Convention on Climate Change.

Emissions by ports and in shipping more generally have been the subject of international regulation ([Tichavska et al., 2019](#); [Tovar and Tichavska, 2019](#)). Particularly important here is the VI Annex of the MARPOL Convention of the International Maritime Organization (IMO) on “Regulations for the Prevention of Air Pollution from Ships.” This was adopted in 1997 and entered into force in 2005 and directly regulates shipping sector emissions of the shipping sector globally. Controls have tightened over time, with limits of sulfur emissions of fuel being reduced to 0.5% from the beginning of 2020. An important innovation of the IMO’s (2019) MARPOL legislation that indirectly affects ports is the creation of Emission Control Areas (ECAs), which are located in areas with high concentrations of coastal population and shipping activity and which apply stricter requirements to fuel content. Thus, whereas sulfur content of fuel is limited to 0.5% of fuel from 2020, in ECAs this limit is 0.1%. An example of regulation more directly affecting ports is the 2014 EU Directive 2014/94/EU that all major ports should seek to install Onshore Power Supply (OPS) (also known as “cold ironing.”), which is the delivery of shore side electrical power to a ship at berth while its main and auxiliary engines are turned off, and LNG facilities.

Ports themselves have been actively adopting strategies to reduce air emissions. In April 2008, the International Association of Ports and Harbors (IAPH) requested its Environmental Committee in consultation with the Regional Organization of Ports for a mechanism to assist ports to abate air pollution and climate change. As a result, 55 ports around the globe adopted the C40 World Ports Climate Declaration, initiating studies, strategies and actions to reduce exhaust emissions and to monitor and improve air quality. In 2014, a new website (www.lngbunkering.org), also promoted by the IAPH, was launched to address the use and bunker of LNG in shipping as an alternative to pursue the reduction of air pollution and negative effects on human health. Moreover, the latest theme for the annual award promoted by European Sea Ports Organization (ESPO) also addresses innovative port projects that lead to environmental improvement for the benefit of the wider port and local community. In Europe, the ESPO provides a platform for port authorities to address environmental management of five selected issues: air quality, energy conservation, noise management, waste management, and water management.

In an effort to go further than IMO regulation, a series of mainly voluntary initiatives have been implemented by port management bodies, such as the Environmental Ship Index (ESI) and the Green Award (GA). The Green Award Foundation was established in collaboration with the Port of Rotterdam in 1994 and GA certificates have been introduced in several ports which provide incentives to encourage compliance with environmental standards beyond existing regulation. Among these incentives are

discounts in port dues and discounts on services. The ESI project, initiated through the World Port Climate Initiative of the IAPH in 2010, identifies seagoing ships that perform better in reducing air emissions than required by the current emission standards of the IMO and is intended to be used by ports to promote clean ships. The ESI formula evaluates emissions from ships based on the amounts of nitrogen oxide (NO_x), sulfur (SO_x), particulate matter (PM), and carbon dioxide (CO₂), and incorporates a reporting scheme on the greenhouse gas emissions of the ship. It also rewards ships that can use Onshore Power Supply (OPS) while at berth. While the majority of ports that have adopted this scheme are European, ports from the United States, Japan, Australia and Korea have also signed up (see <http://www.ppmc-transport.org/environmental-ship-index-part-of-the-international-association-of-ports-harbors-world-ports-climate-initiative>).

In general, environmental charging and differentiation in port and fairway dues according to environmental performance has become an increasingly popular policy instrument in recent years to address negative environmental impacts. Swedish ports, for instance, have adapted to regulation and technical standards by implementing a fairway due rebate system since 1998 (revised in 2005), where dues are differentiated according to the NO_x and sulfur content in fuels. By 2011, 33 major ports in Sweden had introduced the system based on certificates issued by the Swedish Maritime Administration (SMA), and the Finnish ports of Mariehamn and Turku have also joined this initiative. Spain is the only other country in Europe aside from Sweden that regulates environmental charging at national level: in the other countries, these are self-regulated at the level of the port authority. Most of these self-regulated schemes offer rebates on port dues ranging from 0.5% to 20% to vessels that are certified under well-acknowledged indexes and/or certification programs (COGEA, 2017).

The role of differential charging for environmental aims has been also recognized by the recent EU Regulation. Thus, Article 13 of this Regulation states that port infrastructure charges should be set in line with port's commercial strategy and investment plans and comply with competition rules, but permits these charges to be varied in certain circumstances, including more efficient use of port infrastructure and sustainability criteria such high environmental performance, energy efficiency, and carbon efficiency.

A drawback of voluntary schemes is that they may lead to reduced business as a result of increased prices, especially if competing ports act as free riders and do not implement the charging scheme (COGEA, 2017). In order for differentiated port charges to be feasible - in the sense that they do not distort competition and lead to shifts in interport traffic toward free riders - there is a need for a coordinated regulatory framework of a larger area as opposed to a single port authority (Bergqvist and Egels-Zander, 2012). This potential loss of business is in line with the "pollution haven hypothesis" in environmental economics which holds that firms tend to move operations from regions or countries with relatively stringent environmental regulations to others with relatively lax regulations. This issue has been discussed in the context of ECAs by Chang et al. (2018). Coordinated regulation would avoid this problem and permit widespread gains. For example, the study by COGEA (2017) concludes that if external environmental costs are factored in, savings from reduced emissions in ports may outweigh the costs connected with the revenue foregone from reduced port dues.

Emission Trading Schemes (ETS) are also under discussion within the IMO and the EU strategy toward sustainability in shipping. At present, however, policy actions to abate air emissions relate mainly to the quality of fuel and the technological alternatives available. One of the technological options available that directly affects port infrastructure is OPS, which improves the port-city environment in terms of noise, vibration and air emissions. Since 2002, OPS has been implemented in ports in Europe, North America and Asia. The European Union has taken active measures to foster the introduction of the technology, including the co-financing of pilot schemes to facilitate OPS in several Spanish ports (OPS Master Plan: <http://poweratberth.eu/?lang=en>). Despite the technical challenges involved, it appears that this will form part of future regulation in Europe. Thus, a recent document (*The European Green Deal (COM(2019) 640 final)*) published by the European Commission that includes a reference to ports states that "transport should become drastically less polluting, especially in cities . . . the Commission will take action in relation to maritime transport, including to regulate access of the most polluting ships to EU ports and to oblige docked ships to use shore-side electricity."

Finally, the enforcement of environmental regulation depends on where breaches occur. The legally-binding United Nations Convention on the Law of the Sea (UNCLOS) applies at sea beyond national jurisdictions. In ports, on the other hand, vessel compliance with regulation is implemented under the mechanism of Port State Control (PSC), which involves the inspection of foreign ships in national ports to verify that the conditions of the ship and its equipment comply with the requirements of international regulations and that the ship is manned and operated in compliance with these rules (see the IMO website for details: <http://www.imo.org/en/OurWork/MSAS/Pages/PortStateControl.aspx>).

Conclusions

There is an increasing trend in the maritime and port sector toward greater control of logistics chains through mergers, acquisitions and strategic alliances. This has manifested itself in greater vertical integration along the logistics chain as well as greater horizontal integration among terminal operators. This raises the clear possibility of anticompetitive behavior. Moreover, the creation of portfolios of terminal operations at global level and the integration of terminals with shipping lines increase the need for and importance of regulation that can be enforced across wide geographical areas. The recent EU port services regulation is an example of this. As always, regulation must also be careful not to discourage investment, especially in a context where ships are becoming ever larger in size and ports have to compete to be able to provide the infrastructure to cater for these so-called megaships. However, growing environmental concerns at global level and a scenario with powerful global terminal operators that are horizontally and vertically integrated point to a need for coordinated regulation that takes into account the interests of all stakeholders and multiple

levels of governance. Under these circumstances, it is a major challenge for regulators to maintain competitive conditions and ensure environmental sustainability.

Biography

Dr Beatriz Tovar is Full Professor at Las Palmas University and a member of the University Institute for Tourism and Sustainable Economic Development, a leading research team at international level in the field of innovative and sustainable tourist development and a member of its Tourism and Transport Research Unit, a leading research team at international level in the field of Transport. She teaches in undergraduate and graduate (including MBA and PhD) courses regarding the productivity and efficiency measurement for utilities and Transport. She has been actively involved in contracts and research projects with the World Bank, CEPAL, the European Commission or the Spanish Ministry of Transport. She has published in several respected international journals including *Applied Economics*, *Energy Economics*, *Energy Policy*, *European Journal of Transport and Infrastructure Research*, *Fisheries Research*, *Journal of Air Transport and Management*, *Journal of Energy in Southern Africa*, *Journal of Production Economics*, *Journal of Transport Economic and Policy*, *Maritime Economics & Logistics*, *Maritime Policy and Management*, *Research in Transportation Business & Management*, *Tourism Economics*, *Transport Policy*, *Transport Review*, *Transportation*, *Transportation Research Part A*, *Transportation Research Part D*, *Transportation Research Part E*, *Transportation Science*, and *Utility Policy*. She is also a member of the editorial board of *Transportation Research Part E*. She does also act as a reviewer for several international journals such as *Case Studies on Transport Policy*, *Economía Mundial*, *Energies*, *Energy Economics*, *Energy policy*, *European Journal of Transport and Infrastructure Research*, *International Journal of Transport Economics*, *International Journal of Sustainable Transportation*, *Journal of Air Transport and Management*, *Journal of Environmental Management*, *Journal of Shipping and Trade*, *Journal of Transport Economic and Policy*, *Journal of Transport Geography*, *Maritime Policy and Management*, *Research in Transport Economics*, *Research in Transportation Business & Management*, *Revista de Economía Aplicada*, *Science of the Total Environment*, *Sustainability*, *Transport Policy*, *Transportation Research Part A*, *Part D*, and *Part E*, *Utility Policy*, *WU Journal Maritime affairs* and also for international congress such as IAME 2014, IAME 2015, IAME 2016, IAME 2018, IAME 2019. Finally, she is a member of the Editorial advisory board (EAB) for the journal *Transportation Research Part E: Logistics and Transportation Review (TRPE)* and also a member of the Editorial advisory board (EAB) for the journal *Sustainability (Sustainable Transportation Section)*.

Dr. Alan Wall is Associate Professor of Economics at the Department of Economics of the University of Oviedo and a member of the Oviedo Efficiency Group, a leading research team in the field of productivity and efficiency analysis. Alan's research in efficiency and productivity analysis covers several fields including transport economics, health economics and agricultural economics. He has published in several respected international transport journals including the *Transportation Research Part A*, *Transportation Research Part D*, *Journal of Transport Economics and Policy*, *Maritime Economics and Logistics*, *European Journal of Transport and Infrastructure Research*, *Transportation Science*, and *Transport Policy*. He teaches a graduate course in regulation and competition at the University of Oviedo. In recent years, he has held visiting research positions at the University of Connecticut (USA) and the University of Aberystwyth (UK).

Glossary

Liner shipping A regular shipping service offered to different shippers adhering to a fixed and published itinerary
Parcel A shipload/consignment (in shipping)
RoPax Roll-on/passenger (car ferry)
RoRo Roll-on-Roll-off – handling of rolling cargo
Shipper Transport buyer
Shipping line Maritime transport provider
Tramp shipping A shipping service offered on a voyage to voyage basis, often on the spot market

Introduction

The path between origin and destination is obviously at the heart of any transport service. Among the traffic modes, shipping is more restricted than air when deciding on the route but less restricted than road and rail that must stick to paths made up by infrastructure. Navigation on inland waterways, however, follows the principles of the land modes. Equally important and intrinsically connected is the scheduling of services (Christiansen et al., 2013; Norstad et al., 2011) and voyages allocating vessels and deciding upon departure and arrival times, and thus also speed through water and over ground, but also the departure frequency for regular services. When deciding on speed, shipping is less restricted than air that is rather well aligned with the aircrafts' design speed and road with trucks following speed limits set by the infrastructure provider but also temporary road conditions. Rail can theoretically and technically vary the speed considerably, but the mode is hampered by the rigidity of time tables, coordination between trains, and propagating delays in the network.

The first step of maritime route planning is to find and select the customer and the goods (or passengers) to transport. The information about the character of the goods flow in terms of loading and discharging locations, type and amount of goods/

passengers, regularity and the shippers' preferences for transport time, timing, frequency and other logistics parameters is then used for deciding on vessel type and size, potential mix with other cargo or passengers, operating speed, scheduling and, of course, the appropriate coarse route between ports. Using the tools of logistics, this activity is generally performed by the shipping lines' office staff and is here denoted *commercial route planning*.

International shipping is an industry that can rather easily move its registration, management, administration, operations and assets to where the business opportunities are considered best. The main reason for moving the firms' registration is to utilize a competitive tax or subsidy system, and registering vessels in flags of convenience is generally motivated by a more relaxed regulatory framework. Registration of firms and vessels, however, is rarely decisive for vessel routing but *regulatory route planning* considers parameters such as regional and local regulation of fuel, emissions, vessels' technical standard, crew size, and working conditions. In addition, various political conflicts such as trade wars and boycotts restrict how ships can be routed.

The general idea of how to transport the goods between ports stemming from commercial and regulatory route planning is then fine-tuned by vessel crews weighing in information and forecasts of currents, weather, waves, ice, congestion in ports and canals, risks of piracy and political conflicts and other short-term operational parameters for creating a more detailed voyage plan. In this encyclopedia entry, it is referred to as *navigational route planning*.

Some aspects of maritime route planning are generic but the discussion must be broken down into shipping segments for further understanding. The main differences between tramp and liner shipping relate to the number of shippers and connected ports, parcel sizes and the regularity and rigidity of the service. By definition, tramp shipping is offered on a voyage-by-voyage basis whereas liner shipping depends on a network for offering a regular multiuser service. Furthermore, the conditions for route planning are quite different for the tramp shipping segments tank and dry bulk; and the liner shipping segments container, RoRo, RoPax, and cruise. This text is mainly about freight transport, which is the main task for the maritime mode, but passenger transport is included in the RoPax and cruise segments.

The text is structured with a general discussion in three sections on commercial, regulatory and navigational route planning. The following section deepens the rendering in the context of tramp shipping divided into tanker and dry bulk shipping. More specifics on route planning in liner shipping is then provided in a section further divided into the market segments of container, RoRo/RoPax and cruise shipping. The text is finally concluded including some thoughts on how maritime route planning is likely to evolve in the coming years.

Commercial Route Planning

This section deepens the discussion on logistics performance preparing for the more detailed rendering for each shipping market segment. Focus is on the transport service and the goods/passengers rather than the vessel operations.

Market Planning

Before narrowing into the route of a particular voyage, a number of scoping decisions must be taken. A shipping line must first decide upon the general maritime transport market it wants to serve including main shipping segment, port geography, type of cargo or passengers, whether to serve a customer at a time or finding a compromise addressing several customer demand patterns and whether to offer a premium service or cutting corners to offer lowest possible price. A shipping line with wider ambitions might also consider offering door-to-door services rather than confining the market offer to port-to-port. Setting these main parameters of the offer is a strategic activity with a long time horizon that can be denoted market planning.

Service Planning

When the market planning has set the wider boundaries, the shipping line needs to decide upon further details of the offer including which principles to guide the operation of the vessel or fleet to satisfy the shipper or shippers and be competitive and yet securing a positive economic return. Service planning addresses the character of the transport offer at a medium time horizon. Liner shipping is generally more complex than tramp, but not necessarily as planning the ballast voyage repositioning a tanker to a port range with a positive market sentiment when arriving there requires much experience and significant analytic capacity, whereas operating a regular RoPax bridge substitute is fairly straight forward.

Network operation principles can be used to reduce complexity in transport networks. **Fig. 1** shows six network configurations for connecting an origin to a destination directly or via other nodes to facilitate consolidation of people or goods. The configurations assume that nodes can be connected as the crow flies, but in reality the detours taken through nodes are often over-layered by detours taken for other reasons as elaborated on by [Woxenius \(2012\)](#).

Direct link is obviously the simplest configuration and the evident example is a taxi service but much of tramp shipping follows the same principle as do bridge substitute RoPax services. The role model for the corridor configuration is a bus or inter-city rail service with stops along the route. Coastal shipping, container feeder services and barge services on inland waterways apply a similar configuration and so does container shipping between East Asia and Europe with a number of port calls en route. Hub-and-spoke is mostly applied in air transport but there are a few maritime examples found in archipelago ferry services for commuters. Connected hubs is modeled on road-based general cargo consolidation networks, but also applied by inter-continental services between second

Figure 1 Six options for transport from an origin (O) to a destination (D) in a network of ten nodes. Dotted lines show operationally related links in the network designs. In “Dynamic routes”, two alternative routes are shown; in all other designs, the routing is predefined. Source: Woxenius (2007).

tier airports. It also resembles the way transpacific and transatlantic container services are operated with deep sea vessels connecting a few hub ports, from which short sea feeder vessels connect to smaller ports. The container feeder services themselves often operate along the principle of static routes with a fixed itinerary combining a number of ports, of which some are hub ports, like in South-East Asia, the Mediterranean or the Baltic Sea. The most evident example, however, is a public transport service in a bigger city, in which passengers can find their way forward by using different tram, subway and bus lines making up a network. In dynamic routes, finally, transport planners start every new cycle with the current transport demand and optimize the routes. An airport hotel shuttle constitutes a passenger transport application and a typical shipping example is product tankers distributing petroleum product parcels from a refinery to distribution depots along the coast.

Voyage Planning

Unless it is a regular liner shipping departure that follows a pre-set plan, each voyage is coarsely planned in the shipping line office including selecting the particular vessel to use, the main route with order of port calls, speed, deciding on whether to use canals and waters requiring pilots or icebreakers as well as avoiding pirate ridden or war-torn regions. This is a major activity in tramp shipping and it is also performed for ships in ballast repositioning for the next laden voyage. Liner shipping stowage planning is also affected if there are ports along the route that have draft limitations prohibiting the vessel to call if it carries a too heavy load.

Regulatory Route Planning

The general right to navigate on the high seas has a long history. The idea was not new but it was formulated by Hugo Grotius in his work *Mare Liberum* in 1609 but it took considerable time to get the principle generally adopted. By the end of World War 1, when German submarines had launched unrestricted submarine warfare as a response to the British naval blockade of Germany, both actions challenging the Freedom of the Seas, Woodrow Wilson emphasized the right to navigate as the second out of 14 points for reaching a lasting peace:

“Absolute freedom of navigation upon the seas, outside territorial waters, alike in peace and in war, except as the seas may be closed in whole or in part by international action for the enforcement of international covenants” (Wilson, 1918).

Although the general rule is to navigate freely on the oceans, shipping, like all businesses, has to adhere to regulations and some of the constraints are relevant for route planning. Some regulation strictly limits routing, whereas other increases costs of passing certain waters or calling ports and is thus seen as an option fed into commercial route planning.

One example is the Sulfur Emission Control Areas (SECAs) stipulating the maximum sulfur content of the fuel, other types of fuels or use of cleaning technologies to get an equivalent result. Sulfur emission rules differ between seas, which can motivate shipping lines to navigate around an area with stiff regulation. Another example is the slowly stiffening regulation on CO₂ emissions. In 2018, the European Union (EU) implemented the Monitoring, Reporting, and Verifying (MRV) system, which requires shipowners and operators to report CO₂ emissions from their ships both per traffic work (in g CO₂ per nautical mile) and per transport work (in g CO₂ per ton-NM). It includes emissions from the last port call before and first port call after calling a EU port. The MRV system is likely to be the basis when including shipping in the EU Emission Trading Scheme (EU-ETS) and there is hence an incentive to add port calls just outside the EU during longer voyages to reduce the share of emissions that has to be traded under EU-ETS.

A US example of regulatory route planning relates to cabotage. For a hundred years, Merchant Marine Act of 1920, better known as Jones Act, has required that transport between two US ports is carried out by a ship built and flagged in the US as well as owned and crewed by US citizens. Jones Act thus restricts routes combining international and domestic shipments.

Yet another example is that routeing in the Eastern Mediterranean is hampered by difficulties to include port calls in Israel and Arabic states in the same route considering the political tension in the Middle East. Also technical and working condition requirements can differ in different waters and thus affect route planning.

Navigational Route Planning

This section narrows the focus to the day-to-day operations of vessels, which is often done by the crew but increasingly assisted by shipping line offices, information sharing between vessels and by new tools for decision support.

Route Selection

The main route is defined before departure by updating the result from the voyage planning considering more short-term conditions in canals, congestion and labor market conflicts in ports, forecasts for weather, currents, ice conditions and other temporary conditions.

Operational Routeing

During the voyage, the crew takes logistics parameters into account and puts it into an operational reality fine-tuning the route and speed to save fuel but also for operating safely or to catch up lost time (Wang and Meng, 2012). Information is gathered from shipping line offices, from other vessels in the fleet and from other organizations involved in the transport chain as analyzed by Andersson and Ivehammar (2016). Examples of actions are to cancel or change order of port calls, negotiate alternatives with shippers and ports, book slots with canal authorities, pilots, tug and icebreaker operators. During the corona pandemic, for instance, crew replacement was severely hampered forcing staff to stay onboard and finally required ships to reroute to call ports allowing for crew changes.

Operational routeing is also affected by the position and trajectories of other vessels. Radar systems have assisted navigation for decades and transparency is improved by transponders feeding vessel identity, position, velocity and some operational data into the Automatic Identification System (AIS). In addition, traffic management authorities and onshore pilots assist and restrict crews navigating in ports and narrow straits with heavy traffic.

Weather and Current Routeing

In early days of shipping, weather, currents and ice were strict conditions for navigation and mother nature also defined the shipping seasons. Cyclic currents like tides and El Niño and seasonal weather patterns like monsoons in the Indian Ocean and harsh winter storms in the North Atlantic are weighed in already during commercial route planning, but with a short time-horizon crews must align the route and speed over ground to more temporary storms, shifting currents and ice conditions. The water level of inland waterways varies over time, which is obviously closely monitored by barge operators.

Weather routing is the aspect of route planning with most focus on decision support tools (Zis et al., 2020). Weather forecasts are easily accessible, but shipping lines often subscribe to specialized forecasts that feed into the navigation system or to dedicated weather routing applications. The precision of forecasts has increased tremendously with better data capture by satellites, buoys and radar stations on land but also through better meteorology algorithms. Furthermore, data on weather, waves, ice and currents but also operational data is increasingly distributed within fleets to improve accuracy (Andersson and Ivehammar, 2016) but the data can also be distributed by authorities or specialized firms on a commercial basis. This is particularly important to smaller shipping lines.

Weather routing is not only used for reducing bunker consumption, improving safety and crew comfort but also to prolong technical lifetime of ships. One example is that Atlantic Container Line sponsored research on weather routing and used the results to keep operating safely in the North Atlantic with its G3 container-RoRo vessels, which had a reduced structural strength after sailing many years in tough conditions.

If weather or other conditions are particularly harsh prohibiting the crew to keep up the schedule, the new conditions are fed into commercial route planning deciding on options for rerouting or rescheduling.

Tramp Shipping

The majority of tramp shipping constitute an integrated part of large-scale industrial systems adapted to maritime transport with a rail link from a mine or pipeline from a well to the nearest port and the next step of refining the raw material, for instance a steel mill, coal-fuelled power plant or refinery located close to water with an industrial port. Although the industrial system including the

maritime part is comparatively stable over long periods of time, shipping is highly volatile as tanker and dry bulk carriers are generally traded on the spot market.

This section deepens the discussion in the setting of tramp shipping highlighting some specifics for routing of tankers and dry bulk vessels and some characteristic decision situations that occur. The route planning horizon is often relatively short for tramp shipping and scheduling simple when it is provided as just one voyage between two ports for a single shipper. The detailed plan and deviations from it can be negotiated with the customer and the consequences of each option is rather easy to estimate.

Tanker Shipping

For petroleum tanker shipping, the big divider in logistics as well as chemical terms is the refinery. Large single-load tankers bring crude oil to the refinery and smaller product tankers distribute a different oil products to depots closer to the final market. The segments follow different commercial route planning logics. One example of regulatory route planning particular for tankers is that the US Government, deterred by the disastrous effects of the Exxon Valdez oil spill in 1989, required all new tankers calling US ports to be equipped with a double hull. Until the international regulation kept up, it was common for single hull crude oil tankers to call Caribbean ports with refineries and then let newer double hull tankers feed into US ports rather than have a direct route from the oil well to the US port requiring double hull vessels the full distance.

Crude Oil Tanker Shipping

A peculiarity of crude oil shipping is that the load is subject to speculation and can shift owner several times during the long voyage. Following the logistics strategy postponement, the crude oil tanker is often sent in roughly the right direction and then rerouted on the way as the final destination is set by speculators. For crude oil from the Middle East, for instance, final routing decisions for East Asia are typically taken when ships pass the Strait of Malacca and when passing Bay of Biscay for Northwestern Europe.

Voyage in ballast also requires route planning and it is often possible to find a shorter route, for instance very large crude carriers (VLCCs) passing the Suez Canal, which is too shallow for fully loaded VLCCs.

Product Tanker Shipping

Product tanker shipping involves an intricate cargo planning. The hold of the vessel is divided into several tanks that can carry different petroleum products and often also chemicals. Cleaning the tanks is very expensive and the frequency is minimized by planning routes allowing for a sequence of loads from cleaner to dirtier fractions and then cleaning and starting over with clean products. The planning is done for each tank and requires much experience and knowledge of the market to get an efficient sequence of loads.

Dry Bulk Shipping

Dry bulk shipping lines trade in a mix of industrial shipping with long contracts of affreightment for a set transport task and the highly volatile spot market. Dry bulk shipping often has a high portion of ballast voyages but it is more flexible to find return loads than crude oil shipping. Some vessels are specialized for specific cargoes such as iron ore, coal or grain and some are built as flexible combination carriers for oil and dry bulk. The benefits of a specialized or very flexible ship is, however, difficult to reap (Stopford, 2009) and most dry bulkers are built for fitting the requirements of the major bulk commodities to relax the restrictions in route planning. An exception is when shipping lines get contracts of affreightment spanning over the full vessel life cycle such as the one between the shipping line COSCO and the mining company Vale. It covers annual transport of 16 million tons of iron ore from Brazil to China for 27 years from 2018. To put it into perspective, the transport work (in ton-kms) equals 5 years' of transport by all trucks in the EU. A transport task with such a time horizon implies that route planning is more or less confined to navigation. Dry bulk shipping is further elaborated on in the entries 10255: Bulk Shipping Markets: An Overview of Market Structure and Dynamics and 10488: Maritime company freight management/Bulk industry.

Liner-Shipping

Liner shipping is characterized by the use of a fixed and published itinerary (Stopford, 2009), multiple shippers and a strong dependency between vessels serving the same route. It can also be regarded as an art of finding a good compromise between multiple shippers' preferences, considering a wide set of restrictions and yet operating at a profit. Liner vessels sail with a certain regularity and depart although they are not fully loaded. Each ship simply has to fulfill its task in the itinerary. Some cargo like cars and trucks is transshipped using their own wheels, but most cargo is stowed into load units with a unitized interface toward vessels, port equipment and land vehicles. There is hence less focus on the particular commodities but rather the load units in terms of containers, cassettes, semi-trailers and accompanied trucks.

Liner shipping has a stronger connection to hinterland transport compared to tramp shipping. It means that logistics service providers can route the cargo via different ports and shipping services combined with rail shuttles and road haulage to serve a door-to-door market (Tongzon, 2009). Depending on the system level analyzed, the route planning can be very complex including port

choice (Slack, 1985), positioning of empty containers (Song and Dong, 2012) and optimization is a very popular research topic (Christiansen et al., 2013; Wang and Meng, 2012).

Container Shipping

When the container was widely introduced in the 1960s, it was nothing less than a revolution for international trade. It affected routing in the sense that the traffic was concentrated to fewer ports and although many ports have since invested in container cranes, there are prevailing economies of scale stemming from the use of large container vessels connecting a few mega-hubs connected to smaller ports with feeder vessels as in the connected hubs route option in Fig. 1. Container shipping is further described in the entries 10254: Container (liner) shipping, 10482: Containerization and the Port Industry and 10266: Scheduling of Liner Container Shipping Services.

Deep Sea Container Shipping

For routing in intercontinental container shipping, geography and demography affect the tradelanes differently. The transpacific and transatlantic tradelanes are not very restricted by geography but there are, on the other hand, few options for port calls en route so the connected hubs option of Fig. 1 dominates. At the East Asia-Europe tradelane, however, geography funnels traffic through the Strait of Malacca, the Suez Canal and Gibraltar Channel and vessels sail close to shore also when doubling the Indian subcontinent, North Africa and the Iberian Peninsula. It implies that the route can include several port calls in densely populated areas without deterring detours (Woxenius, 2012). The intermediate port calls, in turn, can connect to regional feeder systems serving Southeast Asia, the Indian subcontinent, East Africa and the Mediterranean. Container shipping between East Asia and Europe hence follows the principles of the corridor routing option of Fig. 1 with some elements of hub-and-spoke. As containers are not only moved between East Asia and Northwestern Europe but also between ports along the route, stowage planning easily gets complex. Scheduling is also affected as just a smaller share of the containers are transhipped at each port, comparing to transpacific and transatlantic services with just a few ports at each coast leading to long time in port.

Short Sea Container Feeder Shipping

Feeder shipping operates under rather flexible schedules and feeder routes are frequently changed in terms of which small ports to call and in what order. If too few containers are booked to or from a port, the call can be cancelled at short notice and containers either have to wait for the next departure or moved by land modes to another port. Short sea feeder shipping thus resembles the routing option dynamic routes in Fig. 1 and if it is used for fully intra-regional transport it can use the hub port for hub-and-spoke routing. It should be noted though that also RoRo vessels move containers and increasingly so within Europe.

RoRo and RoPax Shipping

Roll-on-Roll-off (RoRo) move unaccompanied rolling cargo between and within continents and Roll-on-Passenger (RoPax) combine accompanied cargo and passengers on shorter routes. The main commercial route planning issue is whether to minimize the distance over water, often referred to as bridge substitutes, or trying to call ports as close as possible to the main origin and destination of freight and passengers fully using the benefits of maritime transport. This is a multifaceted problem for RoPax services with a truly wide variety of customer demands to consider. Route or speed changes affect voyage time, which in turn can require adaptation of turnaround and departure times and vessel reconfiguration with trade-offs in terms of lane meters versus passenger space, seats versus cabins, and the dimensioning of restaurants, bars and shops. RoPax bridge substitute offer high frequency and operate with short turnaround times whereas RoRo services often are strictly coordinated with the main shippers' industrial system acting as a moving belt.

The main routes are stable over decades and are almost regarded as infrastructure whereas shipping lines can challenge the incumbents with new routes or capture a market opportunity for a season. In some instances, ferry shipping also make detours to ports that are not motivated by the amount of cargo or number of passengers stepping on or off, but to grant the legal right to sell tax-free items. Examples are Åland Islands in the Baltic and Norway in the North Sea. Short crossings often reduce weather routing to the decision whether to cancel a departure for safety and comfort for passenger and freight.

Cruise

Perhaps not downright liner shipping, but the route of cruise ships, finally, is definitely planned ahead. The route planning is based on port visits rather than moving items between ports and often the passengers depart and arrive in the same cruise hub port. Hence, the routing is not necessarily directly between ports, but detours are routinely taken for beautiful scenery like Norwegian fjords.

Summary and Conclusion

This entry discusses how the character of the transport demand, regulation and mother nature affect maritime route planning in general but it has also brought up special routing conditions for individual shipping segments. The route options change over time

as canals are built or extended, rivers and straits silt and, unfortunately, global warming opens up for new routes in the Arctic like the Northern Sea Route between East Asia and Europe (Liu and Kronbak, 2010).

As route and schedule is so decisive for customer satisfaction and costs, voyage optimization systems increasingly support routing decisions by integrating and analyzing a truly wide set of data from sensors onboard, from other vessels in the fleet and from public and private data providers. The improved access to data and the complexity of routing have led to that decisions are increasingly moved to the shipping line offices as master mariners seem to speed up too much not risking delays, but the offices have more comprehensive knowledge needed for deciding on the trade-offs between revenues and costs. But some decisions stay onboard as the master mariner is responsible for the ship, the cargo/passengers and the crew's safety and well-being. Unmanned and automatically navigated ships will change maritime route planning dramatically, but that lies a bit into the future.

Introduction

With the introduction of the container in the 1960s and high growth numbers since then, also the transport parts preceding and following sea container transport have gained in volumes and importance. Initially, these pre- and end-haulage parts of the total transport supply chain took place by unimodal transport, which was most times truck. Since these early days, container transport has grown enormously, leading to also enormous growth in the fore- and hinterland and the use of the inland ports. Truck transport is very suitable to handle the transport in the fore- and hinterland given its good quality, high speed, reliability, and low price. However, its success has also caused certain problems associated with truck transportation to grow to unsustainable levels. Especially external effects such as emissions, noise nuisance, and congestion have grown to unsustainable levels. In response, policymakers have sought to develop policies aiming for a modal shift from single-modal truck to multimodal rail and inland waterway transport. In these multimodal transport solutions, the major part to and from the seaport takes place via rail or inland waterway, next the containers pass an inland port, while the first and last part of the trip to and from the customer usually takes place by truck. The idea is that trucks are disappearing from roads and are being replaced by more sustainable transport solutions. Although this policy has not been very successful in improving the market share of intermodal freight transport (IFT), growth has caused all transport systems to be quite overloaded. Road transport experiences high congestion, rail transport has only limited space for additional rail freight transports and inland waterway transport shows increasingly congestion at locks and bridges. Inland ports and inland container terminals form important elements of the IFT solution and also these ports and terminals do need to cope with limited space and seek efficiencies in their existing operations in order to accommodate further growth of freight flows or expand further, sometimes even by adding different locations. So all in all, transport modes are overloaded and also inland ports and terminals show signs of congestion and often limited expansion possibilities at current sites. This is exactly the moment when synchronomodality starts to play a role in IFT. Synchronomodality seeks a balanced and integrated approach toward all three transport modes (inland waterway, rail, and truck) where the aim is to use rail and inland waterway transport including inland ports to the maximum extent possible and only use the truck when no other options are available. In addition, planning plays a crucial role and this planning takes place at different levels such as freight flows, modes, transport means, capacities, terminals, etc. Therefore the aim of the chapter is to analyze the characteristics of IFT and inland ports and terminals. Next, synchronomodality will be defined and challenges and drivers for IFT will be discussed. Finally, a number of successful cases of synchronomodality will be presented in order to show the potential of synchronomodality for the successful further development of inland waterway transport, inland ports, and terminals.

This article is organized as follows: the first section gives the introduction. The second section discusses the definitions, types and challenges regarding IFT. The third section introduces the new concept of synchronomodality. The fourth section analyses the challenges and drivers for synchronomodal transport, while the fifth section analyses several cases regarding these drivers and challenges. The article summarizes and concludes with the last section.

Intermodal Freight Transport: Definitions, Types, and Challenges

Definition of IFT

IFT (usually involving the transport of intermodal load units such as containers, trailers and continental load units) can be defined in several different ways. First, intermodal transport can be defined as “The movement of goods in one and the same loading unit or road vehicle, which uses successively two or more modes of transport without handling the goods themselves in changing modes”

Figure 1 Main important aspects of intermodal freight transport. Source: Based on Wiegmans and Konings (2015).

(<https://uic.org/combined-transport>). A shorter version of this definition is “door-to-door transport that uses two or more transport modes.” Second, intermodal transport enables the transfer of unit loads from the place of origin to the final destination by combining two or more different transport modes (road, rail, inland waterway, sea, and air). Road transport is then often used for local collection and/or distribution only (www.hupac.com). Morlok and Spasovic (1994) define intermodal transport as “the movement of highway trailers or containers by rail in line-haul between rail terminals and by tractor-trailers from the terminal to receivers (consignees) and from shippers to the terminal in the service area.” In these definitions, it can be observed that transport modes and load units are important elements of the definition of IFT. Jones et al. (2000) define intermodal transport as “the shipment of cargo involving more than one mode of transportation during a single seamless journey.” Hayuth (1987) defines intermodal transport as “the movement of cargo from shipper to consignee using two or more different modes under a single rate, with through billing and through liability.” Especially interesting about these last two definitions is the aspect of single journey and single rate, which connects well with the characteristics of synchromodal freight transport (SFT). In the Fig. 1, the main aspects of IFT are depicted. Incoming freight flows arrive at a maritime container terminal. Next the main transport takes place (via inland waterway) and next the inland container terminal handles the containers. Finally, the end haulage takes place towards the final destination. See also the chapter by Macharis et al. (2020), “10285: Intermodal and synchromodal freight transport.”

Different Types and Classification of IFT

In theory, two types of IFT exist: rail-oriented IFT, where the main haul takes place by rail and inland waterway-oriented IFT, where the main haul takes place by inland waterway. In Europe intermodal rail freight transport is the most important transport mode after truck transport.

The developments for rail freight transport are not that positive in an area of high growth of overall freight transport and in the light of the aimed for market share increase of rail freight transport (https://uic.org/IMG/pdf/2018_report_on_combined_transport_in_europe.pdf). Over the period, tons transported by rail have decreased by almost 5% and the ton-km only slightly increased. Intermodal rail freight showed impressive growth over the period, however, this part of the market carries only a little importance in terms of tons. Important parts of the transported freight by rail are formed by dry bulk, liquid bulk, intermodal transport units, and wagonloads. Intermodal transport units can be further subdivided into swap bodies, containers, trailers on a train, and palletized wagonloads. Strong points of rail IFT are its competitive price if door-to-door solutions are possible and if distances are relatively long, its high level of safety, its fuel efficiency, its ability to carry large volumes, and rail IFT is less harmful to the environment than truck transport. Weak points of rail IFT are its lack of accessibility and flexibility, its bad image, its unreliability, its relatively low speed, and its lower suitability for smaller shipment and smaller load units. Improving the competitive position of rail IFT proves to be very challenging over the last decades. Research by among others Ferreira (1997), and FitzRoy and Smith (1995) show that crucial elements are faster transit times, higher frequencies, and more reliability. In order to realize this, large increases in both the number of connections and the operating costs are required for which the funding and the political approval lack. For a more detailed discussion on rail freight see the chapters “10281: Rail freight” by Woodburn (2020) and “10283: Eurasia rail freight: enablers and inhibitors of future growth” by Templar and Rodemann (2020).

After trucking and intermodal rail freight transport, intermodal inland waterway transport is the third important transport mode. The inland waterway infrastructure network is 40,000 km long (rivers, canals, and lakes), of which almost 20,000 km is concentrated in Germany, Belgium, France, Austria, and the Netherlands (<http://www.inlandnavigation.eu/what-we-do/facts-figures/>). Also 20,000 km of the network is accessible for 1,000 ton vessels while 75% of all inland waterway traffic crosses borders. On a yearly

basis, the barge fleet transports around 550 million tons of freight. Important sectors for inland waterway transport are dry bulk, liquid bulk, containers, general cargo, Ro/Ro, special transport, and push barges. For the Netherlands, inland waterway transport is very important and represents the second mode of “national” transport (in terms of ton-km) after road (Table 1).

Strong points of inland waterway transport are sufficient availability of infrastructure capacity although lock capacity increasingly poses problems. Furthermore, it is the most environmentally friendly transport mode, it is fuel-efficient, it is reliable, it is able to carry large volumes, it is not too expensive if distances are relatively long and door-to-door transport is possible, and its safety is regarded high. Weak points are high investments needed for new barges combined with a long life-time expectancy, lack of accessibility, tendency toward overcapacity, seaport congestion, reliability, low speed, lack of qualified employees, limited role in transport organization, natural constraints (ice, water level changes), and limited flexibility.

The Position of Inland Ports and Terminals in Inland Waterway IFT

Besides the mail haulage by rail or inland waterways, the inland ports and their terminals are important. The role, function, and operation of inland container ports in the total IFT solution is quite important and gets even more important as a closer integration between maritime and inland freight transport systems is occurring where deep-sea ports and also container carriers seek more control over the hinterland. A variety of different scales can be observed as some inland container ports are just simple container terminals while others are much more complex areas that include multiple container terminals, additional logistics zones and a governance structure, such as a port authority that governs the complete area for one or more municipalities. In these inland container ports, besides the core function of container handling other functions such as storage, consolidation and deconsolidation of freight, acting as depot, maintenance of containers, and customs clearance can also be made available. In the freight transport network, the position of the inland ports can vary from a “simple” extended gate of a major seaports that helps accommodate freight flows from large deep-sea ports further inland because in the deep-sea port there is insufficient capacity to large inland ports with own strategies and own networks that not solely depend on major deep-sea ports (such as Venlo and Duisburg).

Challenges for Intermodal Transport

Different challenges exist for IFT posing threats to the performance and operation of IFT. An important challenge is infrastructure capacity. In rail IFT, there is a lack of additional infrastructure capacity (lack of new train paths) and the priority of freight trains also influences the capacity for freight trains. This lack of capacity severely hampers the growth opportunities for IFT rail. The capacity issue also holds for IFT inland waterway but concentrates more on the locks and bridges that not always offer sufficient capacity. The capacity on the waterways (the links) usually is sufficient. A challenge linked to capacity is the availability of funds for the growth of capacity. Large investments are needed in capacity while the funds for these investments often lack (Wiegman and Behdani, 2018). A third challenge is the difficulty of finding qualified personnel which especially in IFT inland waterways is a serious issue. The last challenge is the increasing efforts of truck transport to reduce their emissions and work toward less polluting trucks. This means that also IFT rail and inland waterway have to increase their efforts in order to stay more environmental friendly compared to truck transport. Synchromodality might offer possibilities to work on these challenges and give IFT the next boost.

Figure 2 The main elements of synchromodality. *Source: Authors' own illustration.*

Synchromodality Defined

Establishing an agreed definition of synchromodality has not proved to be an easy task since there is no consensus on a precise definition of this concept. There is, however, a general agreement that synchromodality is about an integrated view in planning and using different transport modes to provide the flexibility in handling freight transport demand in the real time. Therefore synchromodality is mostly defined based on two main concepts (Fig. 2). The first concept is the integrated or systemic view on intermodal network and service design. This implies that—instead of looking at different intermodal services by different transport operators (either barge, rail or truck operators)—we must look into the options from an integrated view and based on the complementary nature of these different modalities (StadieSeifi et al., 2014; Van Riessen et al., 2013).

The second aspect of synchromodality is flexibility (or easy switching). In a SFT service, a contract is made between shippers and a synchromodal transport service provider in which shippers “only” book the transportation service with the agreed cost and quality requirements. Synchromodal transport service providers then decide on which transport modes to use according to the specifications of the customer. Depending on the actual situation and mode availability, the cargo can be distributed over several modalities, enabling the shipper to benefit from the advantages of low cost and sustainable modes and transport provider to benefit from higher asset utilization (Behdani et al., 2016). As a result, synchromodality offers greater flexibility in mode choice. It also improves the reliability, makes the lead time in the transport chains shorten, and increases the utilization of road, rail, and inland waterway.

The essential flexibility in a synchromodal transport system can be achieved only when three other conditions are met. In other words, *flexibility* itself is a multidimensional construct and is composed of three other elements. *Availability* is about the presence of options. The premise of a synchromodal system is an easy and real-time change the modality from one mode to another or from one path to another one based on the network situation and with the aim of optimizing the network utilization. To achieve that, there need to be multiple options available for transporting a container from point A to point B. Without existing those options—which can be primarily caused by lack of infrastructures like rail or inland waterways—a synchromodal system service cannot be defined. The second concept is *Mobility*, which is about the possibility of switching from one modality to the other one. In some case, multiple options for moving a container from point A to point B are available, but the transport planner cannot switch to the best transport modality because there is a high penalty or cost associated with that. A common example of this is the concept of A-modal booking (or Mode-free Booking) in which a shipper gives the right of choosing a modality or even a route for the container to the transport operator (Behdani et al., 2016). In other words, booking transport service is done without specifying the explicit mode or path for transporting the cargo. As a result, the transport operator can freely (i.e., without penalty) choose the appropriate route or mode based on monitoring the whole transport network. As discussed in the next section there might be additional barriers that can make it extremely difficult or even impossible to flexibly switch from one modality to another one.

The third aspect (or driver) of flexibility is *Transparency*. There can be situations in which multiple options or modalities are existing and the transport operator can switch among modalities; yet, because of no visibility or shared awareness about the whole transport network, the alternative best options cannot be found (De Borger and De Bruyne, 2011).

To conclude, the elements of the framework of Fig. 2 describe the necessary aspects or drivers of a SFT system. More integrated view in the design of intermodal network or services will provide more opportunity for synchromodality in IFT. Similarly, providing more flexibility—by focusing on each of the aforementioned three aspects—will facilitate to transform an IFT system into a synchromodal one. It must be emphasized that the concepts defining the synchromodality can be applied to design a synchromodal infrastructure network. In other words, an integrated view is applied in the development planning of transport/transshipment infrastructures (Fig. 3). This includes a long-term strategic view of synchromodal design and is called network synchromodality. A more frequently discussed business model of synchromodality is, however, synchromodal service design which is about designing

Figure 3 Network synchronomodality and service synchronomodality. Source: Authors' own illustration.

transport services (e.g., defining the timetables or contracting with service providers) from an integrated systemic view and providing the flexibility in the design of service.

Challenges and Drivers for Synchronodal Transport

While interest in synchronomodality is growing, there are several challenges in and barriers realizing a synchronodal transport system. These challenges are categorized into four groups as shown in Fig. 4.

Cultural or social barriers are about the view, values, and beliefs of individual actors in a transport chain. Moving toward SFT calls for a mind-shift in all actors in the chain. The primary mind-shift is for shippers by accepting a mode-fee booking business model (Lucassen and Dogger, 2012). Several studies show that—especially for cargos with the high value of time—the shippers are not ready for such a move (Behdani et al., 2019). The other cultural aspect is the mind-shift in transport operators. Emerging a SFT system calls for collaboration among operators working with different modes of transport (Franc and Van der Horst, 2010). These operators (in different modalities) are currently seen as competing service providers. For synchronomodality this competition mind-set needs to be replaced by one that emphasizes on cooperation among different transport operators (looking at the complementary nature of different modes of transport).

Technical barriers are about developing technical platforms for synchronodal planning. As discussed in the next section, there have been several projects in the last few years focusing on developing (IT) platforms. Yet, a trusted platform that supports actors to

securely share their information (e.g., the existing capacity in their network in real time) needs further attention. The other technical aspect is physical similarity of different modalities; for example, for shifting from a rail service to a barge service for a reefer container, the barge should have the power plugs in order to cool down the reefer containers on board (Behdani et al., 2019). Without such a technical arrangement, there is no possibility to change the modality in a synchromodal service.

The organizational and regulatory barriers are the third category of barriers for SFT. Conflicting or inconsistent requirements for different modalities—for example in terms of insurance or customs documentation/process—and lack of standard regulations (or similar insurance rates) for different modalities can be potential legal barriers for synchromodality (Veenstra et al., 2012). Additionally, involving multiple stakeholders—both private and public organizations—in the design and operation of different modalities may obstruct the full potential of synchromodality. This calls for new types of contract settings to share the gains/pains fairly among all actors in a synchromodal network (Veenstra et al., 2012).

Operational barriers are embedded in the common business practices in the IFT. For example, active regional bundling of container flows may provide more opportunities for synchromodality in a specific hinterland region (Lucassen and Dogger, 2012). Yet, some operational constraints like detention and demurrage costs or different cut-off times for modalities may hinder this bundling as well as the possibility to switch from trucking to rail or barge. Additionally, similarity between the administration processes involved in managing different modes of transport can facilitate the transition toward a synchromodal freight transport system.

It should be noted that these four categories of barriers are interrelated. For instance, a business environment in which shippers are hesitant toward synchromodality will not provide enough incentives for governmental bodies to develop new regulations or adapt the existing regulation and processes. This means that cultural barriers can induce legal barriers, which induce further cultural barriers. The interrelatedness of the four categories of synchromodality barriers can result in a chain reaction toward failure, with the IFT system then remaining in its current business-as-usual.

Cases on Synchromodal Transport in Inland Waterway Sector

Table 2 gives an overview of the projects and practical cases on synchromodality. The projects in this table especially include the cases in which IWW was included as a part of synchro-modal service. As one of the first studies on this topic, TNO performed a pilot study on SFT between ECT Euromax and Delta terminals in Rotterdam and two inland terminals (i.e., Moerdijk and Tilburg) using a trimodal service with barge, rail, and road connections (Lucassen and Dogger, 2012). Based on this pilot study, Lucassen and Dogger (2012) presented a framework for synchromodality in five areas: (1) role of shippers (the necessity of mode-free booking as a prerequisite for synchromodality); (2) dynamics (real-time planning and switching among modalities); (3) cooperation and control (the need for cooperation within transport chains and between transport chains); (4) network and organization design (the need for network view instead of point-to-point connections and new business models to stimulate cooperation and network operation); (5) infrastructure use (more efficient use of existing infrastructure and removing bottlenecks—like opening hours of locks).

The other practical case of synchromodality is the European Gateway Services (EGS) by ECT in which a synchromodal transport system delivers containers between the ports of Rotterdam and Antwerp and several inland terminals in the Netherlands, Germany, and Belgium by means of more than 30 weekly inland barge services and 40 weekly rail services (European Gateway Services, 2019). Additionally, the handling of customs formalities is done in some inland terminals (i.e., an Extended Gate Service). EGS is well known as the best practice of defining and implementing synchromodal solutions.

Table 2 also gives an overview and the details of several other projects (and research studies) on synchromodality involving inland waterways. The majority of these projects are focused on the technical barriers for synchromodality. The legal and organizational aspects are still less thoroughly studied domains and call for further attention.

Summary and Conclusion

This chapter discusses the concept of SFT and how it helps in meeting the challenges in using inland waterways as an alternative modality. A framework for defining the SFT is presented. The framework describes two concepts of “Systemic view” and “Flexibility” as the main pillars of synchromodality. Flexibility itself is a multidimensional construct and is supported by “Availability,” “Mobility,” and “Transparency.” The challenges in developing a SFT system and an overview of the projects and practical cases on synchromodality in inland waterway sector are presented. Although the technical barriers for synchromodality are generally addressed, the legal and organizational aspects are still less thoroughly explored and should be centralized in future studies.

Introduction: The Transport of Passengers

The maritime transport of passengers includes two distinct markets—cruise and ferry shipping. These two markets differ for two main characteristics—the typology of vessels used and the nature of the demand served. In fact, cruise shipping uses vessels that can accommodate only passengers (and the crew) while maritime transport service serves a final demand (i.e., the cruise itself is connected to a touristic need rather than a need for transportation). The ferry industry serves a derived demand (i.e., passengers are interested in reaching the arrival destination for their own purposes) and it often uses vessels that can accommodate both passengers and vehicles (Stopford, 2009). These two separate purposes affect the characteristics of the ships as well as their size. International statistics show a global average size for cruise ships of about 52,000 DWT (deadweight tonnage) against an average size of the ferries of about 1500 DWT. Similarly, services on board are substantially different (e.g., hoteling and entertainment services for cruises against essential welcoming services for ferry passengers), making the two markets completely separated not only from a demand point of view but also from the ship supply one. Eventually, the two markets largely differ in terms of international exposure: on the one hand, with only few exceptions, cruise services are organized to connect international destinations; on the other hand, ferry services are mainly provided to connect regional or national destinations (Stopford, 2009). Nevertheless, this latter element does not mean that international connections are excluded from the service market, given that certain world regions are currently experiencing a growing trend in international services as well (e.g., Mediterranean, South East Asia). Because of these general characteristics, ferries often compete against either air transport—especially in case of connections with islands—or rail and road services—in case of coastline connections—but they hardly compete with other maritime passenger services. A notable exemption is the organization of the mini-cruise services that often are substitute of ferry services, promoted with ships that can—at least partially—offer a short cruise experience.

The ferry sector is characterized by specific elements, mainly in terms of ship used, market organization and regional coverage, regulation, and operator strategies. These elements characterize the maritime passenger transport sector in several ways.

This paper is structured as follows: after this brief introduction, Section The Fleet assesses the fleet composition, highlighting the heterogeneity of the ships used for providing ferry services. Section The Service Organization describes current service organization with the aim of showing main areas in which ferry services are developed. Section The Market Organization focuses on the market organization, with the statistics connected to the main shipping companies as well as the different business challenges. Lastly, Section Summary and Conclusions contains a brief recap of main characteristics of the market as well as some conclusive remarks.

The Fleet

Under the kind of vessels deployed perspective, ferries are heavily used in the so-called “Short Sea Shipping” market (Paixão and Marlow, 2002; Wang and Lo, 2008) in which passengers are often transported together either with their own vehicles or with cargo (e.g., trucks, trailers, etc.). Because of this, often ships used in this market could be classified as multipurpose vessels, that is, ships able to provide both basic services for passengers (and sometime even essential hoteling services for specific passenger routes) as well as some cargo services. Thus, ferry ships are often classified together with the Ro-Pax vessels (i.e., ships able to transport passengers as well as trucks and containers), Pax/Car carriers (i.e., ships able to transport both passengers and vehicles), and with some Ro-Ro vessels (i.e., ships that mainly carry cargo through the loading of vehicles and trucks but that from time to time could be used for passenger services as well).

From a port point of view, traditional ferries as well as Ro-Pax are characterized by a low need of infrastructures in order to be productive: in fact, they need only a wharf to drop a ramp for the embarkation and disembarkation of passengers and vehicles. These conditions make ferries a mode of transport very popular, in some cases the primary transport mode, in developing coastal countries as well as in connecting remote regions. Moreover, the absence for a need for technological handling or welcoming facilities, has

promoted the use of such kind of transport service as a basic way to promote marine transport among different regional areas (Baird, 2007; Medda and Trujillo, 2010). This is reflected in the diversified size and characteristics of the vessels (Lai and Lo, 2004)—in order to serve popular markets, ferries, and Ro-Pax can have a capacity of more than 1500 people, despite this the average vessel size is of about 200 passengers (with some small ferries with a capacity of just 20 passengers), showing a great variety of vessel typologies that need to co-exist in order to serve the different market segments (i.e., touristic destinations, remote areas, islands).

The flexibility of this maritime service has been often highlighted by international agencies (e.g., UNCTAD) and local national governments (e.g., Indonesia, Philippines, Greece) as the main way to interconnect island communities. Moreover, several countries promoted mixed passenger/cargo transport services through ferries in an attempt to provide alternatives to congested coastal highways, as happens in certain European and South American countries (Albanese et al., 2013).

This segment of the maritime transport is extremely diversified as testified by the characteristics of the fleet both in terms of the capacity of the vessels deployed—from very small vessels to very big ones and in terms of the kind of vessels (i.e., Ro-Pax, Ferries, Car/Pax carriers, Ro-Ro). Currently, about 4000 ferries are in service, dedicated to exclusive passenger transport only. Moreover, there are about 2300 ships specialized in Car/Pax transport, about 1000 ships classified as Ro-Pax, and 600 ships that regularly belong to the Ro-Ro market and that potentially could be used into the ferry market as well. Therefore, the overall “ferry” segment could count on about 8000 of ships, representing about 10%–15% of the overall commercial ships [these potential overlaps in the utilization of the ships in multiple market segments often generate issues in having precise market statistics on specific businesses, as highlighted by Albanese and Cusano (2012)].

Given that the service provided can sometime be performed with really small ships connecting several couples of ports, the market is currently not concentrated, registering more than 3000 companies worldwide that own and operate either ferries, Ro-Pax, or other similar passenger ships. Among these companies, almost 70% of them owns less than 5 ships, with operations that span only at regional and national level and no presence in international markets. Thus, in terms of economic characteristics, the disposability of a ferry fleet doesn't represent a significant entry barrier to the market since the ships may be easily moved from a market to another. Moreover, there are scope economies in the industry but they are not so relevant, as demonstrated by the existence of several small companies, while the existence of a second-hand ferry market contributes to reduce the time lag between the decision to enter a particular market and the moment the fleet is ready to operate.

Overall ship building trends are presented in Fig. 1, highlighting another peculiarity of the ferry industry in respect to other shipping markets: the capacity of the ferries did not improve in the last years—in both terms of average passengers carrying capacity and DWT—as it happened for all other main ship types (e.g., cruise and container ships are still registering an increase in size)—this peculiarity is mainly linked to the maturity of the market as well as for the stable demand of transportation that reduces the need (and the benefits) of further pursuing economies of scale. On the one hand, the characteristics of many markets (i.e., small island ports) played also a big role on this limited increase in size, given the infrastructural limitations and the low level of demand. On the other hand, the growing need of providing differentiated services (e.g., mix cargo/passenger services) or multi-call solutions, affected the introduction of bigger ship in terms of DWT for accommodating trucks or for the provision of extra-services without affecting the passenger carrying capacity.

Fig. 1 shows the overall trend in terms of average ship capacity of newbuilt ships in terms of both passengers and DWT and also the number of ships entered into the service in the referenced year—one notices that many fluctuations affect the market, a peculiarity of all shipping sectors.

Fig. 2 reports the age of the ferries currently in service, disaggregating the ships per regions in connection to the nationality of the vessels. Most of the vessels are deployed in Europe (29% of the total) followed by Asia. In terms of age of the fleet, the vessels deployed in the market are relatively old (more than a third is older than 30 years) with half of the old ships registered by EU companies. Similarly, all the companies belonging to the main regional markets (i.e., Europe, Far East, South-East Asia) have half of their ships built more than 30 years ago. “Young” ferries are relatively uncommon, with about 15% of the ships having less than 10 years.

Figure 1 Trends in liner passenger fleet. Source: Authors' elaboration from Clarkson-SIN (2019).

Figure 2 Distribution of ship age per registered flag of the ferry. Source: Authors' elaboration from Clarkson-SIN (2019).

The Service Organization

Overall, ferry transport services are organized as a liner service connecting two or few ports behaving as floating bridges. The ferry industry is particularly developed in geographical contexts with long coastlines, islands, and archipelagos as in Europe (e.g., in the Mediterranean Sea and in the Northern Sea), in Southeast Asia, in Japan, and in the African Great Lakes region, just to mention a few. Fig. 3 shows the position of the vessels classified as "Ferry" worldwide. As it is possible to see, most of the ships are deployed either in Europe—in the Baltic and North Sea regions and in the Mediterranean Sea as well—or in Asia—North-East Asia and South-East Asia. These two regions account for most of the ship registered worldwide as well as of their movements (in the map they are represented by the *white-dotted circles*). Other important areas for regional ferry traffic are North America and the Middle East (*light grey-dotted circles* in Fig. 3).

Given the distribution of the services, worldwide fleet appears quite concentrated in Europe and Asia, as shown in Fig. 4.

Figure 3 Density of ferries worldwide. Source: Authors' elaboration from Clarkson-SIN (2019).

Figure 4 Worldwide fleet distribution. Source: Authors' elaboration from Clarkson-SIN (2019).

Conventionally, ferry direct connections last for no more than 48 hours (longer journeys are considered as cruise services). The importance of this kind of transport service is given by the volume of passengers served; according to the Interferry's website—the association that groups over 200 ferry operators worldwide—every year almost 2.1 billion of passengers are transported by ferries.

The Market Organization

Considering the top 100 companies per number of ships owned, Fig. 5 shows the vessel distribution in terms of number of ships as well as in terms of passenger capacity. Considering the overall market, the sector appears quite disperse, with low-market concentration (the HHI index is lower than 200, considering all main competitive variables, that is, number of ships, DWT, pax capacity) that highlights the dynamics of the sector as well as the possibility for many operators to be competitive into the market. In terms of

Figure 5 Fleet distribution in terms of ship number and passenger capacity. Source: Authors' elaboration from Clarkson-SIN (2019).

Figure 6 Ships' flags in DWT. Source: Authors' elaboration from Clarkson-SIN (2019).

competition in providing alternative services, most of the point-to-point routes are traditionally served by only few operators (often just by one) and this actually reduces the level of actual competition on the market, despite the dispersions of the sector. The presence of few operators on many routes is often linked to either regulatory regimes that reduce the possibility for several operators to be present into certain markets (e.g., limits to assure service quality) or to the level of demand that reduces the attractiveness of providing perfectly competitive services (You and Park, 2017; Kizielewicz et al., 2017).

Fig. 3 highlights how, in terms of ship numbers, Asian operators are market leaders, with ships that mainly operate in South East Asian markets. Despite this, most of the vessels in operation in South East Asia are relatively small. In fact, the ranking in terms of ship capacity is quite different: most of the top 10 companies operate in Europe, especially in the Mediterranean Sea.

In terms of ships' flag, Fig. 6 shows the main flags for the ferry market, in relation to the size of the ship deployed. As it is possible to see, main flags are related to either European Union Countries (more than a third of the market) or main insular Asian countries (i.e., Indonesia and Japan).

In terms of services offered, the passengers related markets are characterized by a unique capability to diversify the offer of transport, not only through the supply of mixed services (i.e., Ro-Pax, Pax, Car/Pax) but also through the use of different speed, ships, and complimentary services. Given that the main purpose for using a ferry is the arrival to a certain destination, as per other modes of transport, the possibility to offer different trip durations generate diversified markets, in terms of both price and frequency. Often destinations are offered in competition among few different operators—or even by the same operator—but the service is perceived as different due to the different time spent on the ship, allowing for the creation of competing markets. This element constitutes a quite peculiar characteristic within the maritime transport sector, given that traditional freight services are not often diversified in terms of speed. The speed diversification is often linked to the possibility of finding different kind of ferries deployed on the same route, as in the case of the catamarans (that allow operators to travel faster than through traditional ships).

Moreover, the economic and social role of the ferry in satisfying transport needs has often been linked to specific national interests, such as the connection of remote regions that pushed national authorities to protect local industries as well as to influence the planning of the service schedule and characteristics. Because of this, many countries apply strict legislations to enter into their local markets, i.e. a reserve based on the national flag or the nationality of the shipowner. These restrictions, that represent a peculiarity in the international nature of the shipping industry, are often linked to the need to establish strict service standards (e.g., service frequency, fixed price) in order to allow the use of ferries as primary mobility solution for the remote communities or the island inhabitants.

Another important characteristic that differentiates the ferry market from other shipping sectors is that—given that most of the services are offered regionally—most of the ships are designed to be optimized on the basis of specific local needs. This affects both the size and the overall design of the ships. Thus, specific characteristics of the ship may change from market to market. This peculiar element helps the operators to offer different services that do not only allow passengers to reach the designated destination but also to sell extra activities on-board (e.g. night trips with hotel rooms, sightseeing). The possibility of offering alternative services allows the operators to provide loop services with multiple calls (e.g., Fjord service in Norway) or mini-cruise experiences (e.g., connecting only touristic destinations and offering extra-services onboard) used by passengers not only for moving from a place to another but also as an essential part of their own holiday (Albanese et al., 2013; Mathisen and Jørgensen, 2012).

While the point-to-point service is still the main organizational scheme for this shipping market (e.g., direct connections to an island from a mainland port), the multi-calls services are often linked to specific regional needs or—as mentioned above—they might act as a potential selling strategy for operators. This peculiarity is particularly relevant for serving specific touristic markets (e.g., mainly in Europe and South East Asia) or whenever the demand for certain locations would not allow an economic viable solution for providing the direct service all the year round. In fact, in case of strong seasonality or unbalanced transport flows, multi-calls services are often used as a solution to constitute an economic viable market. In case of un-balanced flows, an alternative to the multi-calls service is to provide mixed services, such as in the case of Ro-Pax ships and other not dedicated ships.

Among the industry trends, two are especially worth mentioning: the introduction of innovations and the improvement of safety, namely in some regions. The drivers of innovation in the ferry market are the increasing awareness of the environmental footprint of the sector together with the need to be more efficient as possible. In this sector innovations mainly refer to the design and building techniques together with the materials used and the propulsion system. Also international legislation (MARPOL—Annex VI) pushed the sector to be more green and sustainable lowering the limits of nitrogen oxides (NOx) and sulfur oxides (SOx) due to the combustion of fuel initially in four areas—the so-called Emissions Control Areas (ECAs)—and in the future in other regions. It is noteworthy that these emission control areas particularly involve coastal regions and then the ferry sector is greatly impacted. This contributes to explain why the ferry sector may be considered the early adopter of relevant innovations as the adoption of LNG (liquefied natural gas) as ships' propeller, but some companies are testing also the use of methanol in their fuel mix, as well as dual fuel systems and the use of batteries for port maneuvers.

The second trend refers to the enforcement of a stricter regulation of the sector, mainly in the developing countries, in order to reduce, and hopefully avoid incidents and casualties (You and Park, 2017). In particular, the efforts go toward an improvement of the skills of seafarers together with an improvement of national legislations and controlling procedures in order to raise the safety and security standards of the world ferry industry.

This introduces to another feature of the industry that is the role (and type) of regulation in the ferry sector. As above mentioned since in most cases ferry services are the solely transport means to connect islands with mainland some regulation is needed if the production of the transport service is not sufficiently profitable, moreover the cabotage services traditionally were restricted to the national flag. Things are changing at least in some regions, as in the European Union, toward the opening of the market to competition of foreign ferry companies and the flagging out of the fleet in order to comply with a less strict rules (with reference to the nationality of seafarers, for instance). Moreover, the sector needs some forms of regulation because in most cases the degree of competition is often relatively low. In fact, a ferry service competes with another ferry service operating on the same shipping route, or a similar (i.e., connecting couples of ports close to each other) shipping route, and competes with road and air transport where this competition is feasible. This means that in most cases the number of maritime operators competing each other is extremely low, thus the need for relevant Authorities controlling for the abuse of dominant positions in the market.

Summary and Conclusions

Marine transport reports and studies are often focusing on either the cargo sector or the cruise market—nevertheless, the passenger transport sector represents an important development factor for many world regions. Often used to limit the environmental impact of the road transport as well as to provide essential links to remote regions. The heterogeneity of the locations served makes the fleet composition quite peculiar: with ships that fails to achieve big sizes and relatively old vessels. The heterogeneity is not only guaranteed by the geographical location of different served destinations, but it also depends on the purpose of the travel (i.e., commuting or tourism) as well as on the possibility to offer mixed services (e.g., as in the case of the Ro-Pax).

Given its strategic role, the ferry market is often highly regulated and characterized by national champions, with a concentration of interests in key countries. This concentration in terms of flag nationality does not prevent the market to avoid concentration in terms of ship capacity, even if few alternatives are provided in relation to specific routes (i.e., the market concentration is only possible on specific point-to-point services).

Eventually, as anticipated above, the key ferry market characteristics can be summarised by the presence of several local markets that affect the ships used (in terms of number, size and technology) as well as the number of operators competing among each other. The presence of strict regulations and the “social” role of the ferries, make this market peculiar within the shipping sector with a relevant regional role that is always linked to assure a “mobility” need of passengers rather than trade (e.g., cargo)/other economic activity (e.g., leisure), as it happens for most of other shipping sectors.

Introduction

Cruise shipping has witnessed an uninterrupted growth and unstoppable globalization trends over the last decades. The globalization of cruise activities is highly supported by profitable cruise lines who have endorsed economies of scale and advanced segmentation, in order to offer innovation and schedule new types of itineraries, and not least, by the desires and strategies of cruise ports to host more cruise activities. It is also advanced by changes in the demand side, in particular the growing internationalization of cruise passengers' source markets. With the positive direct and indirect impacts diffused to the port cities or nearby touristic destinations, cruise seaports are gaining importance. The interest in hosting more cruise calls and cruise passenger movements has been supported, in general, by broader communities and decision makers. Still growing cruise business, like any other economic activity, is also associated with externalities raising social, economic, and environmental questions and challenges for cruise port and the surrounding areas.

The reader is being introduced to the chapter with a short definition of the term "cruising," followed by an analysis of the evolution of a globalized industry. Then the chapter reviews the key challenges and strategic issues of the cruise industry today: the geography of cruise shipping, market concentration, the presence of economies of scale, market segmentation, passengers source markets, and the cruise ports and the destinations that have developed an interest in advancing their cruise activities. Finally, it highlights the importance of sustainability, in particular the socially and environmentally responsible growth, as a strategic issue for the cruise world.

What is Cruising?

Cruise is a mixture of maritime transport, travel and tourism services, facilitating the leisure activity of passengers paying for an itinerary and, potentially, other services on board, and including at least one night on board on a seagoing vessel having a capacity of at least 100 passengers. Transportation (the cruise ship) is the core element of the experience instead of a simple conveyance.

Cruise shipping has first established as the transportation of pleasure-seeking upper class travelers on seagoing vessels offering one or more ports of call in the United States and the Caribbean. Today this is a highly efficient global business. Modern specialized ships which are radically different from cargo vessels, the use of an increasing number of cruise ports of call and turnaround ports, so as to provide their customers excellent in-port and destination experiences, and convenient departures from proximal embarkation cities, are fundamental tenets of the modern cruise industry.

This is an activity-taking place in specific markets, each having its own regional characteristics, with the Caribbean and the Mediterranean being the most important. As such, the cruise industry must address multiple considerations related to on-board amenities, itineraries, ports of call, and shore excursions.

Uninterrupted Growth and Globalization

Since the late 1960s, when specialized vessels of speed and comfort replaced the last liners, cruise shipping has witnessed uninterrupted growth. This growth is the result of a remarkable resilience in the face of economic, social, political, or any other crises that regularly challenge both shipping and tourism sectors. While economic recessions had a major impact over maritime cargo shipping, cruise lines and cruise ports managed to “cruise through the perfect storm” (Peisley, 2012), the global financial crisis of 2008–09 and the Costa Concordia loss. In 2018 a total of 28.2 million people took cruise vacations in one of the cruise regions of the world (North America, Caribbean, South America, Mediterranean, North Europe, Australia, Asia, Africa). In total, 10 years before the number of people that had embarked on a cruise were just 11.8 millions (Fig. 1).

This rise of cruising passengers has been the outcome of the renewals and rising capacity scale of cruise vessels, the improvements in shipbuilding, ports, and the growing interest of destinations that allow for planning of more complex itineraries, the sophistication and specialization of the product offered. Thus the 2019 cruise industry outlook of Cruise Lines International Association (CLIA, 2019), is projecting that more than 30 million single persons will cruise worldwide in 2019. Five years earlier, forecasts had projected this milestone to be reached in 2024.

The starting point of cruise geographical expansion dates back in the early 1970s; to a certain extent modern cruise shipping was invented in Greece by the pioneer cruise line Epirotiki Lines and the aggressive expansion strategy endorsed by its owner Mr. Potamianos who identified the limits of the East Med and decided to plan itineraries at the other side of the Atlantic. Proximity to the major passenger source market (United States) led rapidly to a focus on the United States and the Caribbean that was destined to provide the basis for a remarkable growth and expansion of cruising.

A seemingly unstoppable globalization is highly supported by (1) the profitability of cruise lines; (2) economies of scale; (3) the growing segmentation of cruise shipping; and not least, and (4) the desires and strategies of cruise ports and destinations to host more cruise activities.

Globalization of cruise shipping is based on three types of itineraries structured by cruise lines: (1) perennial, responding to a region that is served throughout the year due to the resilient demand (with high/low periods) and stable weather conditions; (2) seasonal, to serve periodical market potential in periods with good weather conditions; and (3) repositioning, between perennial or seasonal markets (Rodrigue and Notteboom, 2013). Deployed vessels are involved in these different types of itineraries, so as to allow maximum capacity utilization in combination with the maximization of earnings per passenger and lowering of expenses (mostly via lower fuel consumption). Beyond the geographical distribution of passenger source markets, the factors affecting the deployment patterns include the need to match brands and ships to source market demographics; the links with airlift, and landside transportation; the opportunity to balance marquee destinations with lesser known gems, or that of developing new routes and generating itineraries for new markets, the potential shore excursions revenues comparing to on-board spending; fuel sourcing, availability and cost consideration. All these are examined in parallel with the time, speed and distance formula in order to decide where and how to deploy cruise ships.

The Geography of Cruise Shipping

Cruise lines restructure their deployment strategies trying to better understand what fits best in each case, and what are the strategies responding to the global presence of cruising. Differences among the markets and regions exist, the most obvious being the variance of profitability. The emerging multiregion industry development is directly linked with a changing geography.

The deployment shares of each region are a combination of the existing demand, and the willingness of cruise lines to develop new markets. Looking at the capacity of the cruise vessels deployed in each region, Caribbean stands as the dominant, with 34% of the global capacity. The Mediterranean Sea is the second biggest region, with a share of 17%. The nonMediterranean European market reaches 11%. While it has been for long standing as the third major region of all, today it is the fourth in the respective ranking, given that in the very recent years the Asian market—in particular China—experienced a record breaking growth (11%). The deployment of increased capacity, combined with the opening of sales offices by many cruise lines in China, Hong Kong, Korea, Singapore, and Taiwan resulted in a growth of cruise activities in Asia from 1.3 million in 2012 to almost four million in 2020. The growth is mostly based on the number of Chinese cruise passengers, which is as big as all other Asian markets combined.

Market Concentration

The three largest cruise lines, Carnival, Royal Caribbean, and Norwegian represent 80% of a highly concentrated cruise shipping industry. Carnival Corporation, with its nine different brands controls 47% of the global cruise market, Royal Caribbean Cruise Line and its three different brands control approximately one quarter, Norwegian Cruise Line Holdings is the owner of three different brands representing 9.5%, while the MSC owned vessels represent a 7% market share. Approximately 30 more cruise lines are currently in operation.

The top two corporations consolidate different brands aiming to cover a variety of market segments. Beyond different and potentially more effective corporate entities, this allows for differentiated services to be offered and the marketing of each brand as a unique of its kind, captivating a larger part of the demand.

Cruise Fleet: Economies of Scale

Economies of scale have been a key future of modern cruising. Today, the biggest cruise ships have a capacity of 6687 passengers, with the capacity of each of the 50 biggest cruise vessels in operation having exceeding 3000 passengers. The average dimension of a cruise ship is over 200 meters long, 26 meters beam, and 3220 passengers capacity, though standard deviation is big and such numbers need to be treated with caution. The average capacity of cruise fleet exceeded 2000 passengers for the first time in 2002, and 3000 passengers in 2006. The current order book suggests a clear trend of stabilization, though this does not include potential withdraws from the market: out of the 24 new vessels to be delivered in 2020, 6 will have a capacity that of more than 4000 passengers, and 3 of more than 2000. In total, 4 of the 24 vessels to be delivered in 2021 have a capacity of more than 5000 passengers. In 2019 the 407 ships provide 600,000 berths capacity, while in 2027 the number it is expected to increase to 472 ships and 785,000 berths.

Market Segmentation

The growth of cruising has led to market segmentation. Different types of vessels, associated with different amenities offered on board and ashore, define types of cruises offered, in turn having as target different groups of potential cruisers. Attempting to further penetrate the market, cruise lines, or specific brands of the bigger corporations, are present in one or more, of the major segments, aiming to expand the social and age groups they target, but also to generate repeaters (past cruisers that decided to return).

Contemporary cruises are popular amenity-packed cruises for people looking for lots of activities and a great value. These mainstream cruises rival land based vacation by offering a comprehensive and amenity filled vacation, inclusive of accommodations, meals, and entertainment, in a casual environment, with newer (or extensively renovated) ships offer modern design and comforts, and many more activities. Premium cruises are more upscale cruises also offering many amenities, with increased focus on refined service and more space. Priced inclusive of accommodations, meals, and entertainment, premium cruises value still exceeds or rivals the best packages offered by upscale hotels and resorts. Luxury cruises are defined by the highest levels of quality and personalized service offered on luxury cruise ships and ashore to exotic ports. Expensive when compared to the rest of the industry, luxury lines deliver value by offering more inclusive pricing than other cruise lines and opportunities to travel to exotic destinations. A fourth market segment is specialty cruises. These focus on a destination niche or a special style of cruising including expedition-style cruises, sailing ships, and a growing number of river cruises. They visit some of the world's most remote and unspoiled places to offer a unique experience that guests find educational and adventurous (on the structures of the cruise industry: Pallis, 2015; also contributions in Pallis et al., 2014).

Source Markets

The North American market has always been, and continues to be, the largest and most stable market since the beginning of modern cruise. The actual number of Americans that cruise per annum, mostly with American brands, is estimated to be 14 million passengers. There are also Americans who cruise on European brands in the Caribbean and Europe. Yet, while growth has slowed

in recent years, the low levels of cruise penetration to the local market support projections for further expansion of cruise in the region.

Beyond North America demand for cruising is mostly expressed in Europe. According to 2018 data, about 7 million European decided to cruise, with almost one out of four living in United Kingdom and Ireland. A total of 5 million of passengers came from Australasia, Asia, South America, and Middle East and Africa. Even though these higher percentages are to a certain extent the result of the small penetration levels of cruising in the particular markets in past years, it is also indicative of the advancement of stakeholders' strategies aiming to expand cruising in the particular areas.

Cruise Ports and Destinations

In all regions, ports and destinations have developed an interest in advancing their cruise activities. This is not least to the association of cruising with considerable financial contribution to the port cities or nearby touristic destinations. With the significance of the societal integration of ports with the port-cities rising, cruise is part of respective agendas of port authorities and other port managing organizations. In several parts of the world they have moved from multipurpose terminals or temporary docking facilities toward specialized terminals, in order to act as ports-of-call, and whenever possible as home-ports hosting the, financially profitable, departure, and conclusion of a cruise (Niavis and Vaggelas, 2016). A growing interest by third parties, including cruise lines, to invest in port facilities has followed (Pallis et al., 2018).

Among the core issues to be addressed by cruise ports are the availability of adequate infrastructure and the organization of the cruise terminal operations in an efficient way. Cruise ports need deeper and lengthier docks in order to facilitate the new generation of cruise ships efficiently. The necessity of new infrastructures poses significant challenges especially to those ports that are facing land scarcity or the need for regular dredging of their basin. In the latter case there is a need to minimize potential impact on the sea flora and fauna (through land reclamation) and find the best way for processing and use of the dredging operation products.

Beyond matters worth consideration in all ports, such as number of berths, water and sewage facilities, customs, agents, pilots, security and immigration processes, gangways usage etc., additional ones are present in the case of homeports. The development of transport and tourism capacities is also critical. These concerns need to be addressed following a better understanding of the exact implications that the enduring increase of the size and capacity of cruise vessels and the resulting scale of operations produce.

The optimal planning of cruise ports and their terminals enables the most sustainable operations possible. Inevitably this has brought in the agenda of cruise lines and port managers the issue of long-term arrangements. The parameters that would enable a location, or a port, to secure a long-term commitment of cruise lines that would provide the motive to proceed to product and process adjustments need to be defined. Destinations and ports seek ways to reach ways of collaboration with cruise lines toward this end and broader expertise on what needs to be done toward this direction is essential.

Berth allocation is a long-term planning issue for ports with key social implications. The practice refers to the advance planning of which cruise vessels will visit the given port a specific day for a specific timespan. Given the limitations imposed by the geographical distances between ports included in an itinerary and the lengths of cruises, the phenomenon of many operators berthing for the same hours is not rare. The problem of berth allocation is even more important in the case of smaller, secondary, cruise ports. In small picturesque destinations cruise calls might mean the relatively unpleasant situations of a crowded location at certain days or hours, even distortion of other tourist activities. In bigger ports this might take the form of congestion at the time of arrival of bigger ships on which thousands of people are cruising. The arrival of two average size cruise vessels at a given port means more than 6000 passengers disembarking at the same time. Hosted passengers might increase without an increase of the number of cruise calls. Yet, congestion in small and medium destinations is in some cases produced simply because of small additional number of calls. Without effective planning, during some days these destinations are subject to the pressure and the negative effect of too many passengers that can hardly be accommodated in a way allowing for a positive experience. The fact that in several cases the presence of cruises is marked by seasonality deteriorates the problem that smaller tourist attractive destinations face.

Local communities also endorsed at large, if not universally, the idea of hosting more cruise activities. Admittedly, passenger and crew spending contribute significantly to the cruise hosting economies. Cruise lines expenditures for goods and services in support of their operations, along with a number of other indirect and/or induced positive effects, provide additional motives for hosting more cruise activities. According to the Cruise Lines International Association, in 2013, a total of 114.9 million onshore visits by passengers and crew generated \$52.3 billion in direct expenditures at destinations and source markets around the world. These expenditures generated a total (direct, indirect, and induced) global output of \$117.1 billion. The production of this output required the employment of 891,000 full-time equivalent employees who earned \$38.5 billion in income. In the United States alone, the total impact of cruising grew by 26% since 2009, comparing to a rise of 14% of the GDP over the same period. In Europe, a number of economies (i.e., United Kingdom and Ireland, Germany, Italy, Spain, Scandinavian countries, and France) enjoyed cruise spending that in total (i.e., direct, indirect, plus induced) exceeds one billion Euros annually.

The Sustainability Challenge

The aspirations to host more cruise activities are increasingly combined with the strategic importance of sustainable growth; a combination that, ironically, is to a great extent founded on the achievement of the desirable growth.

The gigantism of cruise ships and the multiplication of cruise itineraries, implies a growing number of passengers arriving at a destination with one call alone, posing significant challenges on cruise ports and destinations hosting them. The “contemporary cruise” segment of the sector, that represents more than 75% of cruises, is offered by vessels that exceed in capacity the 3000 passengers/ 1000 crew threshold. Beyond the need for further infrastructure, this implies mass arrivals of tourists at local destinations, concerns for overcrowding, congestion, but also needs for massive operations, considerable footprint, and needs for receiving quantities of waste (for the Mediterranean case: [Pallis et al., 2017](#)). As a result—justifiably or not—local communities have started questioning the unqualified growth of cruising, which had for long been taken as a beneficial development. While the benefits, in term of spending at destinations, are profound this growth might be associated with congestion and a number of related externalities to be addressed.

A condition to enable local communities to extract the most benefits from the rapid cruise market growth is the definition and endorsement of the best practices and policy options at the disposal of cities, ports, and related stakeholders in order to mitigate the externalities produced by cruise shipping, such as traffic or environmental ones. The existing challenges to be addressed are of operational, social, and environmental nature.

Overall, for the cruise world sustainability implies a holistic management addressing issues related to three main pillars: (1) the economy, (2) the society, and (3) the environment. Since many different stakeholders are involved in this process, a critical factor in supporting sustainable shipping is the understanding of all parties concerns, needs and expectations. It is increasingly acknowledged that a strategic approach—involving constructive dialogues, partnerships, synergies, even joint Research and Development (R&D) initiatives—are some of the key instruments toward this end.

Securing most of the potential local gains via an expansion of the cruise activities requests a consensus of how this might be done and how it might be integrated with the local economic development strategies. Destinations and cruise ports have no unlimited spaces for the development of all different activities that they might wish to advance. There is frequently a restriction of space, either at the city or its waterfront, or at the port. The antagonism of different actors and industries to maintain or increase the shares of the space they use is not rare.

The development of cruise activities, or just cruise terminals might be associated with restrictions to residents’ access at the waterfront. On the one hand, the growth of the industry is based not only on the modernization of existing infrastructures, but also on the presence of new facilities and the spatial expansion of the terminals and the cruise related activities. On the other hand, waterfront development is appreciated in many cases as the way to preserve alternative uses and respect traditions of the cities. Given this appreciation, citizens’ objections to develop tourist activities or related infrastructures (parking slots, restricted access zones etc.) are not rare. The definition of the principles to be adopted and the parameters to be examined would secure a balanced approach.

The same stands true for port development. The limited port zone marks imply choices as regards a wide spectrum of activities that might develop. As multipurpose terminals are not anymore a viable option of cruise activities development, the growth of cruise sustaining results in a potential interference with other maritime transport markets. Cargo ports also seek to spatially and functionally expand so as to improve the level of their own integration in supply chains. Stakeholders involved in these markets would like to see biggest parts of the port devoted to their activities, rather than the expansion of cruise ports. A balanced port planning needs to take into account contradicting potentials of different segments development. How this might be done is a question deserving attention.

Cruise terminal site location is the question that follows. Which site, in which way, should be planned cannot be decided apart from broader destination or regional planning. When several potential port sites can be considered, broader goals such as spreading tourism to new areas, help strengthening infrastructure, create tourism routes, provide investment for key facilities are all part of the equation. Plans for other sector development and for other forms of tourism create cumulative effects. The forms of involvement of stakeholders in location choice and, when essential, spatial and traffic planning, is increasingly important.

The planning of the port and the hosting of cruise activities does not, however, end at the gate of the terminal. The transfer of passengers from the terminal to city and transportations related to shore excursions are conversely important. Efficient location choices are conditioned by the efficiency of private, or public, transport strategies (i.e., services provision to the terminal but also avoid interference with urban road traffic when a cruise call arrives or departs). Location choices are also linked with the capacity of several tourism related industries to connect and the urban tourism strategies that tourism organizations and other relevant decision makers have underway.

Thus resolving most of the above problems demands more than an agreement on some technical issues (i.e., berth allocation details). It also demands the development of two types of coordination. The first one is the coordination between cruise ports and cruise lines in order to synchronize the system at the port and the operations taking place at the port terminal. The second one is the coordination of tourist destinations, including local public authorities, museums, retailers and, foremost transport service providers (coaches, buses, taxis) and travel related industries, so as to create smooth embarkation and disembarkation processes and passengers flow in the destination. Even port arrangements such as the berthing planning cannot be efficiently implemented if there are no means to involve other actors at the visited destination so as to orchestrate the entire cruise supply chain.

Reversing Social Perceptions

The expansion of cruise activities has not left unaffected the image of cruising. The elite activity of some passengers per year has been replaced by the mass transportation of thousands of cruise passengers at once. A community’s decision to seek cruise ship visits

requires a number of industries to be involved but will also affect many, either directly or not. Besides, cruise is not dissimilar with the impacts generated by any other tourism development on the milieu and services of visited communities and sites. It might displace current activities by other tourists or by local residents, causing changes in costs, access, and variety. These changes can be positive or negative, that is overloading dock facilities or causing improved ones to be built; creating new services, or pricing the locals out of existing ones. The same change may be viewed as positive by those who benefit and negative by those who may not benefit. All these lead to societal approaches that conceive cruise growth being associated with the deterioration of the quality of life.

Aesthetics have turn to a major issue, as did overcrowding of marquee destinations. A marquee destination that has experienced the negative effect of such approaches is Venice. A ban on large cruise ships passing through the center of Venice was imposed in late 2014, preventing all ships over 96,000 gross tons from sailing to the city's main cruise terminal, and limit the number of bigger ships over doing so to five per day. The debate had gained momentum as citizens and local protest groups were discontent with the presence of the bigger vessels, arguing that they produce pollution and result in substantial levels of emissions, with the acid nature of the pollution thought to be potentially speeding up the erosion of the city's medieval buildings, which are already sinking into the lagoon surrounding Venice, itself an UNESCO heritage site. Even with the real environmental assessment pending, the image of giant vessels next to traditional buildings led to an overheated reaction by local communities; aesthetics has come to play, and cruise liners had to limit number of big ships to Venice.

Other marquee destinations including Barcelona, Dubrovnik, Santorini, French Riviera have experienced similar issues. Barcelona port authority had to substantiate the benefits of cruising via several studies in order to gain the "justification" of its cruise operation, Dubrovnik decided to limit the number of arriving tourists (8000 max) per day at the historical city, Santorini put the same threshold (8000 max per day) to cruisers arriving per day, while French Riviera ports limit the arrivals to 5000 cruisers per day.

Whether these challenges are unsubstantiated or not, these are conceptions and perceptions that have to be addressed in order to achieve sustainable growth. Cruise is inextricably linked with the carrying capacity of a destination, a concept applicable in tourism development strategies, that is, the ability of the destination to absorb tourism before negative impacts are felt from host country, or the maximum number of people who can use a site without causing unacceptable changes to physical environment or affect negatively the quality of visitors' experience. Of course, answering how many cruise passengers can be hosted or how many can be wanted are questions associated with several parameters (i.e., who decides, which are the management objectives, which are the attributes and capabilities of the destination) all of them associated with what local communities perceive.

Limitation of Environmental Externalities

In recent times the emerging question is how cruise shipping, ports and the related economic chain can operate efficiently, within a socially responsible and acceptable framework (Pallis and Vaggelas, 2018). The various environmental externalities refer to the handling of waste produced, water quality, air emissions, noise, and soil, whereas other issues (i.e., constructions that alters natural or build environment, fauna, energy resources etc.) are also part of the relevant agendas.

Addressing two key externalities produced by the provision of cruise shipping and the hosting of vessels and cruise passengers at cruise ports stand today as priorities. The same externalities are illustrative of the need for discussion and conclusions on measures to take place at international level. These externalities are waste management, and the various forms of emissions, including air and noise emissions.

Overall environmental issues with reference to cruise shipping and those with reference to cruise ports are strongly interconnected. Thus the tools, measures, and policies to combat the externalities caused by these two industries require a holistic study and approach developed internationally. Reports, studies, and essential inventories of measures for internalizing external costs are another field, beyond regulations that the international level discussions might advance facilitating growth of cruise activities.

Conclusions

An uninterrupted growth of cruise activities has been recorded for every single year, for more than three decades, supported by an unstoppable globalization trend. What started as a local industry, in the Caribbean and North America, has eventually turned to a global one. Today globalization refers to both supply (offer of cruises) and demand (internationalization of passenger source markets) sides of cruising.

Regional variants exist and the fundamentals of growth are not similar around the globe, these revealed when comparing the details of the trends in the traditional North American market, with the maturing European market(s), or the booming Asian one. The latter stands currently as the major force toward further growth. The same details also reveal that intraregional dynamics go hand-in-hand with substantial intraregional shifts of cruise activities.

Specific business strategies work in support of growth and globalization—such as taking advances of economies of scale in shipbuilding, modernization of product and fleets, market segmentation, and innovative itinerary planning. The adjustment of ports to serve these strategies and the desires of port-cities and linked tourist destinations to enjoy the benefits produced work also in favor of these trends.

The aforementioned developments fuel a growing interest in further understanding the structures and implications of the tremendous growth of cruise activities, the sophistication and the geographical span of the sector is present. The externalities of cruise activity, in the light of the increased social awareness, are a field that the cruise port community needs to develop “green” strategies in order to mitigate the key externalities produced in and outside the port area due to the continuous cruise activities growth. Such strategies are beneficial not only from an environmental and a social, but also from an economic perspective, improving the potential and sustainability of such development.

Introduction: IMO as the Global Leader of Maritime Regulation but Challenged by Unilateral Initiatives

Shipping is certainly one of the most globalized industries with an intrinsic international dimension at different levels. Vessels evolve through different seas and oceans, move between different countries and therefore jurisdictions. Linking continents, shipping underpins the global economy and from commodities to finished products, sea carriage enables countries to satisfy their needs in raw materials and to export their production all around the world (read 10476: Introduction to Maritime Transport). According to the 2018 Maritime Review (UNCTAD, 2018), around 11 billion tons were carried by sea in 2017 and sea traffic is expected to grow in coming decades.

Considering the international context of maritime activities whether for shipbuilding or ownership, operation, manning, inspection and survey, an international regulatory framework has quickly been necessary. In 1948 the United Nations (UN) adopted a convention establishing the first specialized agency devoted to maritime matters: the International Maritime Organization (IMO). Entered into force in 1958, the IMO has progressively become the worldwide leader of maritime regulation involving the largest shipping nations and accounting for 172 member states and three associate members. Approximately 80 nongovernmental organizations (NGOs) and 65 intergovernmental organizations representing a wide variety of interests have consultative status and can attend IMO meetings. It is generally admitted that their contribution to IMO work is valuable notwithstanding some critics against the harmful effects of lobbying.

IMO is now a sexagenarian institution having adopted more than 50 conventions and protocols, more than 1000 codes and recommendations mainly focused on safety, security, prevention, and control of pollution from ships, compensation and related legal matters. Whereas successful achievements to date, especially as regard maritime safety, some persistent weaknesses remain and more particularly on ships' environmental footprint. In reaction to the IMO's slow pace on this topical issue, national policymakers have followed suit with unilateral legal frameworks calling into question the universal and uniform application of maritime regulation as promoted by IMO.

This study aims to take stock of IMO progress since its creation and to identify key weaknesses where action is necessary. It suggests which possible orientations maritime regulation has to follow in order to meet the current challenges of shipping confronted to the fundamental stakes of the 21st century. This paper is organized as follows: after this introduction, the second section deals with the key features and drivers of maritime regulation while the third section contemplates its main pillars. The fourth section highlights the current fragmentation of maritime regulatory framework versus the stakes of harmonization. An assessment of the IMO's successful achievements and persistent insufficiencies is carried out in the fifth section. Finally, some concluding remarks are provided in the last section.

The Key Features and Drivers of Maritime Regulation

The Key Features of Maritime Regulation

One often ignores the key features and drivers of maritime regulation. Maritime regulation is a large concept made up of different legal components. It implicitly includes maritime law and law of the sea. Maritime law on the one hand, is simply defined by all rules

dealing with navigation undertaken by sea. It is focused on vessels, maritime operators and related contracts such as contract of sea carriage, contract of chartering, insurance, or assistance. Maritime law mainly governs private business and solves the fundamental issues of torts. Maritime law comes from different sources beyond the sole IMO instruments: the Comité Maritime International or the United Nations Commission on the International Trade Law have contributed to the adoption of significant rules often influenced by English law. On the other hand, law of the sea is a body of rules on the use of the seas and oceans. Codified by the famous 1982 UN Convention on the Law of the Sea, it defines the state territorial waters and other key areas (e.g., internal waters or economic exclusive zones), it determines the right of states to control navigation, to fish or to mine oceans. Compared to maritime law, law of the sea shows a greater public nature insofar as it deals with sovereignty of states. While their rules are complementary, maritime law mainly addresses private relationships and law of the sea frames both relationships between public entities and between public and private stakeholders. Maritime law is recognized as a field of expertise, old traditions and specific provisions notably with regard to the limitation of ship-owners' liability. In case of marine casualty (collision or pollution for instance), in case of claims for property damage (e.g., cargo loss), in case of claims for loss of life or personal injury, the ship-owner is legally entitled to limit his liability. Numerous international conventions set out this strong principle that features the ship-owners' regime of responsibility and that confirms the singularity of maritime regulation. The 1976 Convention on Limitation of Liability for Maritime Claims and its 1996 Protocol or the International Convention for the unification of certain rules of law relating to Bills of Lading (1924) are famous instruments with a wide scope of application that lay down the key principles of this specific liability regime not always understood and often criticized by cargo interests. Accordingly, maritime regulation taken in the wide sense, encompasses maritime law and law of the sea.

The Key Drivers of Maritime Regulation

Concerning the drivers of maritime regulation, they are numerous and show different natures (Fig. 1). For decades, there is no doubt that the first driver has been repeated accidents. Regulators have indeed adopted new rules after the occurrence of such accidents and depending on their root causes. One can observe that IMO's strategy has mainly been reactive and barely proactive. Nevertheless, new drivers have progressively emerged. Environmental awareness is certainly the second driver but still raised by accidents. A long series of oil pollutions and tanker groundings have made the headlines from the 1970s to 2000s: *Torrey Canyon*, *Amoco Cadiz*, *Exxon Valdez*, *Agean Sea*, *Sea Empress*, *Erika* or *Prestige* which are the well-known, have constrained the IMO to adopt fundamental regulatory instruments (Wijnolst and Wergeland, 2009). In 1973 IMO launched the International Convention for the Prevention of Pollution from Ships (MARPOL) amended by Protocols in 1978 and 1997. At the same time, the first unilateral regulations were implemented by key players such as the United States. The famous 1990 "Oil Pollution Act" (OPA) for instance pointed out that IMO rules were not strict enough to enhance maritime safety and to prevent oil pollution. Even though the IMO could not adopt the same stringent US standards, the UN Agency has maintained its efforts to address safety and environmental concerns by enacting several major instruments, as we shall see in the following section. However, the third driver of maritime regulation is closely linked to unilateral initiatives. When a large country or a group of countries such as the European Union (EU) decides to adopt a regulation with transboundary effects, that is to say applicable to foreign ships, it can contribute to a positive evolution of international rules even though it calls into question the IMO's leading role. This has been verified for double-hull requirement imposed by the EU after the *Erika* case (Carpenter, 2012) and the recent regulation on CO₂ emissions (Fedi, 2017). These two initiatives have constrained the IMO to modify its own rules and to set higher standards.

The last and the most controversial driver is certainly the influence of certain lobbies on maritime regulation. This influence has recently been highlighted especially against IMO environmental policies. Notwithstanding their consultative status in the decision-making process, a 2017 study demonstrated that some NGOs representing industry sectors such as the International Chamber of

Figure 2 The three pillars of maritime regulation. *Source: From the author, 2019*

Shipping, the World Shipping Council, and the Baltic and International Maritime Council have hindered the adoption of climate change measures (InfluenceMap, 2017).

The Three Pillars of Maritime Regulation: Safety, Security and Environmental Protection

The IMO's slogan "Safe, secure and efficient shipping on clean oceans" summarizes the three pillars of maritime regulation: safety, security, and environmental protection (Fig. 2). These three complementary elements do not belong to the same history in the IMO development and one assumes that two stages of maritime regulation have existed—a "traditional" era as well as a more "contemporary" period—where a number of instruments have been developed. We will merely recall the most important regulatory tools.

The Traditional Era: "Safety First"

The first "traditional" stage has indubitably been ship safety that concentrated the greatest attention over the second half of the 20th century until the 1980s. While safety still represents a significant concern in the 21st century, other issues have constrained the IMO to diversify its policy measures.

Maritime safety encompasses a wide number of topics related to the ship herself, her typology (bulk carrier, oil tanker, container ship and passenger ship), her crew, equipment, cargoes, and her external environment. The key objectives are to continuously improve the operational conditions of navigation both in normal or emergency situations, to reduce pollution and more generally, to prevent casualties leading to detrimental consequences for crew, passengers and properties (cargoes and vessel itself).

Adopted in 1914 in response to the *Titanic* disaster, the famous International Convention for the Safety of Life at Sea (SOLAS) was revised in 1974 and many times after with the aim of enhancing new stricter safety rules on board. The binding International Safety Management Code that governs the management of ship operation safety (Chap. IX of SOLAS), the automatic identification systems (AIS) capable of providing information on the ship to other vessels and to coastal authorities automatically or the recent International Code for Ships Operating in Polar Waters (Fedi et al., 2018) are relevant illustrations of the constant evolution of SOLAS in line with new challenges in maritime safety. Thanks to the tacit acceptance procedure, an amendment to SOLAS enters into force within 18 to 24 months after its adoption unless, before that date, objections to the amendment are received from an agreed number of Parties. It enables rapid implementation of new maritime rules. It has recently been the case with the Verified Gross Mass rules on packed containers adopted in 2014 and entered into force 1 July 2016 (Fedi et al., 2019). SOLAS currently represents around 99% of the world tonnage. One cannot forget the 1966 Load Lines Convention that took into account the potential hazards present in different zones and different seasons with the aim to ensure adequate stability and avoid excessive stress on ship hulls as a result of overloading. Moreover, it has to be mentioned the 1972 Convention on the International Regulation for Preventing Collisions at Sea that provided guidance in determining safe speed and the conduct of vessels operating in or near traffic separation schemes. A Search and Rescue (SAR) Convention, adopted in 1979, completed the previous instruments. This major convention established an international system that covers SAR operations providing assistance for the rescue of persons and vessels in distress.

Regarding the human element, the 1978 Convention on Standards of Training, Certification and Watchkeeping for Seafarers set out standards for the seafarers' competence. This strategic instrument has regularly been revised by amendments with the purpose of enhancing requirements on the professionalism of seafarers. Considering that the human factor generally represents more than 90% of accident causes, training and experience of crew members are two strategic components of maritime safety.

To conclude these synthetic developments, we can consider that IMO has framed a robust and comprehensive regulatory framework covering the key aspects of maritime safety that classification societies closely monitor throughout the ship's life (IACS, 2015; read 10491: Ships Classification). Numerous rules are in force, whatever the vessel's position and situation. The designation of separation traffic schemes, vessel traffic services, ship's routeing, and places of refuge have allowed significant positive outcomes in terms of accident prevention. While casualties still occur, one observes a long-term downward trend of total losses for the period 2008–2018. 94 losses occurred in 2017 and 46 in 2018 compared to 151 in 2008 (ALLIANZ, 2019). However, some gaps remain. For instance, few international rules govern safety issues of ports and oil-platforms. Their specific status and geographical position still impede the development of international maritime regulation. In addition, with the development of IT systems, new safety challenges arise especially with regard to autonomous ships that will profoundly disrupt safety systems and patterns.

The Contemporary Period: Environmental and Security Concerns

Environmental Protection

The “contemporary” stage of maritime regulation started with the environmental awareness in the 1970s even if the 1954 International Convention for the Prevention of Pollution of the Sea by Oil initiated a greener path (read 10257: Shipping and the Environment). Nevertheless, the environmental shift has been forced by bad circumstances: oil spills. From 1970 to 1980, 25 oil spills over 700 tons occurred and IMO had to respond. In 1973 the IMO established the Marine Environmental Protection Committee (MEPC) and adopted the well-known International Convention for the Prevention of Pollution from Ships (MARPOL) and its Protocol in 1978. As SOLAS, MARPOL is governed by the tacit acceptance principle that allows a rapid entry into force of new amendments. Updated several times, MARPOL initially focused on the Prevention of Oil Pollution (Annex I) and Noxious Liquid Substances in Bulk (Annex II). The scope of application of MARPOL has been enlarged to different sources of pollution less media hype but also with significant negative environmental impacts: Harmful Substances Carried by Sea in Packaged Form (Annex III), Sewage (Annex IV), and Garbage (Annex V). Notwithstanding the global warming concern, regulatory provisions on atmospheric pollution from ships were only implemented at the end of the twentieth century with the 1997 Annex VI—Prevention of Air Pollution from Ships that entered into force in 2005. This latest text has concentrated a hot topic of debate in recent years. Modified regularly since its adoption, the Annex VI mainly imposes limits on different greenhouse gases (GHG)—in particular sulphur oxide (SOx) and nitrogen oxide (NOx), emissions from ship exhausts as well as particulate matter (PM)—and prohibits deliberate emissions of ozone depleting substances such as halons and chlorofluorocarbons. More stringent provisions on SOx and NOx emissions in specific areas with fragile ecosystems called “Emission Control Areas” (ECAs) have been established (e.g., Baltic Sea, the North Sea, North America, the United States Caribbean Sea, the Virgin Islands, Puerto Rico and Saint Pierre and Miquelon). The Mediterranean Sea, the Black Sea, the Norwegian and Barents Seas are potential ECAs. In addition, the Revised Annex VI implemented a Technical Code, which set limits on NOx emissions from diesel engines depending on their date of construction. Regarding CO₂ emissions, the IMO introduced mandatory energy efficiency rules in 2013 representing the first major step against the reduction of the most prevalent GHG. This regulatory framework is based on two main pillars: the “Energy Efficiency Design Index” aiming at requiring for different ship types a minimum energy efficiency level as regards CO₂ emissions per capacity mile and the “Ship Energy Efficiency Management Plan” for managing, improving and monitoring the energy efficiency of vessel operation (read 10258: Energy Efficiency of Ships). However, experts and IMO itself, recognize that these operational measures will not be sufficient to “satisfactorily” reduce GHG emissions in light of maritime growth. A latest amendment of Annex VI on data collection system (DCS) for fuel consumption entered into force in 2018 (Fedi, 2017). The purpose of this mandatory DCS is to collect ships' annual consumption by fuel type. In accordance with the values declared, the IMO shall produce an annual report to the MEPC summarizing the data collected. Despite this important progress, no decisions have been made as regards market-based measures such as bunker fuel levy or emission trading schemes and consequently, shipping is still without CO₂ restriction targets while decarbonization is more than ever a pressing issue (Psarafitis, 2018). However, MARPOL can be considered as a successful instrument representing around 99% of world tonnage for Annex I, II, III, and around 97% for Annex VI (October 2019 status).

Other key instruments have been adopted focusing on significant environmental concerns for marine preservation. Some of them are particularly important notably the 2001 International Convention on the Control of Harmful Antifouling Systems on Ships, which prohibits the use of harmful organotin in antifouling marine paints entered into force in 2008 and the 2004 International Convention for the Control and Management of Ships' Ballast Water and Sediments (BWM). This instrument aims to prevent and minimize the introduction of harmful aquatic organisms and pathogens from ships' ballast water tanks that is considered as one of the four greatest threats to the world's oceans. Once established, invasive marine species get out of control and can drastically modify marine ecosystems.

There is no doubt that the numerous regulatory measures on vessel-sourced pollution illustrate the commitment of the IMO toward protecting environment. In total, 21 IMO instruments out of 53 are indeed focused on environmental issues. One observes significant positive outcomes regarding oil pollution for instance and mechanisms designed to compensate damages such as the International Oil Pollution Compensation Funds. Nevertheless, one can be skeptical on many points and particularly on the slowness of certain topical concerns (Monios, 2019). The BWM Convention that governs prevention of aquatic invasive species only entered into force 13 years after its adoption. The Hong Kong International Convention for the Safe and Environmentally Sound Recycling of Ships adopted in 2009 is still not enforced (only 13 ratifications up to October 2019) while environmental and

working conditions are problematic in numerous ship recycling yards notably in India and Bangladesh. We will examine more closely these aspects in the fifth section.

Maritime Security

Maritime security is the second key aspect of the contemporary era of maritime regulation while piracy is an age-old issue. Two key instruments deal with security. The first is the 1988 Convention on the Suppression of Unlawful Acts against the safety of maritime navigation (SUA Convention) entered into force in 1992. The aim of this text is ensuring that appropriate action is taken against persons committing unlawful acts against ships such as the seizure of ships by force, and acts of violence against persons. The SUA Convention is completed by the Protocol for the Suppression of Unlawful Acts against the Safety of Fixed Platforms located on the Continental shelf. The second key regulatory framework is the famous 2002 International Ship and Port Facility Security (ISPS) Code. As a comprehensive security regime for international shipping and port facilities, the ISPS Code is a response to the perceived threats to ships and seaports in the wake of the 9/11 terrorist attacks in the United States and other specific events against ships. In the early 2000s, Al Quaida considered the shipping industry as a priority target and several terrorist attacks occurred notably against an American destroyer the *USS Cole* in Aden killing 17 crew members in September 2000. Two tankers endured the same scenario in oil terminals, the *Silk Pride* in Sri Lanka, seven people died (October 2001), and the *Limburg* in Yemen, killing one seafarer (October 2002). The ISPS Code has profoundly modified ports management. It has had numerous positive impacts such as an overall better control of the port area and a safer working environment. No major terrorist attacks have been observed since the implementation of the ISPS Code.

Nevertheless, with the development of IT systems, ports and ships are more and more connected in the cyberspace. Vessels are equipped with increasingly sophisticated IT systems such as AIS, e-navigation tools, and ports are also using numerous IT tools notably port or cargo community system (PCS-CCS) and dematerialized customs procedures. A new significant security threat has consequently appeared: the cyber risk. Stakeholders are particularly exposed insofar they are ever more interconnected. In 2013 the Port of Antwerp was targeted by mafia that used hackers to take control of the PCS in order to hide their drug smuggling. In June 2017 the world's largest shipping company Maersk was the victim of a cyber-attack. It caused computer breakdowns paralyzing online bookings and heavily disrupted the operation of several large container terminals especially Rotterdam, New York-New Jersey, and Jawaharlal Nehru (near Mumbai) for two weeks. Maersk decided to transparently communicate on the consequences of the attack and reported around USD 300 million of loss. Accordingly, shipping companies and port authorities are now aware of the cyber risk and take its management very seriously. In July 2017 IMO thereby promulgated the Guidelines on Maritime Cyber Risk Management (MSC-FAL.1/Circ.3) providing high-level recommendations on cyber risk management to safeguard shipping from cyber threats and vulnerabilities.

Regarding piracy, whereas one observes a downward trend off the Horn of Africa, West Africa, and Asia still face piracy and armed robbery acts. In 2018 201 incidents were reported showing a marked rise in attacks against ships and crews compared to 2017. In total, 143 vessels were boarded, 141 crew members taken hostage, 83 kidnapped, and 8 injured (ICC-IMB, 2018). The Gulf of Guinea concentrated the highest number of attacks. While oil tankers are still a privileged target, a wide range of vessels are also concerned by these attacks. Whereas several IMO instruments aiming at preventing piracy and illegal acts of violence against ships are in force, for example, Codes of Conduct (Djibouti in 2009 and Yaoundé in 2013) or the Best Management Practices, supported by dedicated international institutions such as the International Maritime Bureau, piracy remains a recurring phenomenon. Solutions are not only at sea but, above all, ashore. Unfortunately, the concerned states do not have the appropriate means or do not want to prevent and suppress acts of piracy and armed robbery at sea.

Fragmentation Versus Harmonization of Maritime Regulatory Framework? A Polycentric Response

According to the IMO "because of the international nature of the shipping industry, it has long been recognized that action to improve safety in maritime operations is more effective if carried out at the international level rather than by individual countries acting unilaterally and without co-ordination" (IMO, 2013). Consequently, the IMO promotes harmonized rules intended to be recognized and implemented by all. This principle is contradictory to the principle of Common but Differentiated Responsibilities and Respective Capabilities in accordance with the United Nations Framework Convention on Climate Change, Kyoto Protocol, and World Trade Organization rules. Nevertheless, the principle of uniform and global application of IMO rules is called into question and not only with regard to other UN governing principles.

Unilateral maritime regulation and private instruments have progressively emerged in different countries and regions. The United States have led the way over a period of time in particular as regard oil pollution from ships. With the 1990 OPA enacted after the *MV Exxon Valdez* accident, the United States demonstrated that unilateral regulations could have a crossborder impact since foreign tanker vessels had to comply with OPA provisions especially in terms of insurability in case of damage to the marine environment. Defining a global regime of liability both for shipowners and terminal operators, the holistic dimension of the OPA has never been reached at IMO level. The EU followed suit in the aftermath of the *MV Erika* oil slick in 1999 phasing out single-hull tankers that compelled IMO to accelerate its own timetable. More recently, the EU decided to set up a system for monitoring, reporting, and verification (MRV) of CO₂ emissions (Regulation 2015/757) that implements a close control of ships' fuel consumption and CO₂ emissions (EP, 2015; Fedi, 2017). In 2016 the IMO reacted in launching its own DCS (Resolution MEPC 278(70)), although diametrically different and less ambitious. Beyond the abovementioned rules, private instruments have also flourished both through

port authorities such as the World Ports Climate Initiative or from shipowners with the Clean Cargo Working Group with the same aim to improve ships' environmental footprint.

However, it seems that this fragmented patchwork splits up maritime regulation and weakens its coherence. While our ambition is not to give to our readers an unequivocal answer, one observes that the centre of "legal gravity" has greatly changed over the last few decades and IMO is no longer the unique custodian of shipping rules. A polycentric governance of maritime regulation is underway, particularly at an environmental level (Gritensko, 2017; Ostrom, 2010; Van Leeuwen, 2015), and this process cannot be stopped since local, national, or regional legislations have clearly demonstrated their efficiency in terms of rapid implementation and complementarity compared to international ones (Gilbert and Bows, 2012). Even though we are convinced that harmonized rules can guarantee a level playing field and avoid distortion of competition, universality has turned into a traditional myth of maritime regulation rather than a reality shaping the coming years of the 21st century. The adoption process of maritime regulation at the international level is indeed too slow to address topical issues that require appropriate and short-run responses.

Closing the Gaps Between Successful Achievements and Persistent Insufficiencies

Notwithstanding successful achievements of decades of incremental maritime regulation, the key question is how to enhance them and how to correct the persistent insufficiencies. First, with regard to positive outcomes, it is noteworthy that IMO instruments have contributed to a significant decrease in pollution from ships and marine casualties. Recent statistics clearly highlight these trends. According to 2019 Allianz Safety and Shipping Review, 46 losses occurred in 2018 compared to more than 200 in 2000 representing the lowest number of losses ever reached. Considering that the IMO is the smallest UN agency with a modest budget (€38 million in 2017), one can consider that these results are better than satisfactory. Moreover, it should be recalled that the enforcement of IMO conventions depends upon the Governments of Member Parties and experience has shown that some states have been negligent or reluctant to adopt and ratify certain instruments. This has significantly delayed the implementation of valuable regulatory tools and constrained states to adopt policy responses. The establishment of Port State Control (PCS) in different regions has illustrated the necessity to respond to shipowners' negligence and their substandard ships (Cariou and Wolff, 2015). Whereas the number of substandard ships has significantly shrunk, the recourse to flags of convenience remains a strong tendency of the shipping industry. Shipowners still want to operate their vessels with low taxes and low social costs in order to maximize their profits.

Considering the current situation of maritime regulation, a plea in favor of a more efficient, more transparent and more holistic legal framework is required. First, it is clear that IMO's slow pace on different key issues is no longer acceptable. Concerning ballast water management, more than 40 years of "wait-and-see" policy have dominated this topic. It is obvious that the same strategy is pursued for ships' CO₂ emissions (Bows-Larkin, 2015) that constituted a certain legal loophole of the scope of application of MARPOL until 2013. The same criticism is applicable for ships' recycling since the Hong Kong Convention is still not in force and most shipowners take advantage of this situation in flagging-out their vessels prior to releasing them to dismantling yards located in low-cost countries with little concern for labor conditions and environment. In the same vein, while the IMO adopted the famous Polar Code (Fedi, 2019; Fedi et al., 2018), it is also acknowledged that the Arctic Ocean requires stronger protective measure such as the designation of Particularly Sensitive Sea Areas and ECAs (read 10268: Arctic Shipping). Second, greater transparency could be encouraged through maritime regulation. A governance by disclosure could contribute to a better image of maritime transportation. While the EU has already moved in that direction with MRV Regulation, the IMO has still not adopted this path so far (Fedi, 2017). The IMO's slowness and incapacity to take decisions on topical concerns discredit its judicial status. Prof. Monios considers that "there are fewer places to hide for lobbyists and those arguing in bad faith for solutions known to be sufficient" (Monios, 2019). Third, a more holistic legal framework would be useful. The best example is the situation of seaports. These strategic facilities are still not fully incorporated within the IMO regulatory framework while a recent interest by the organization, which hosted the first-ever dedicated event in 2018 recognized that "port industry faced many challenges that mirrored those faced by the shipping community" (IMO, 2018). Few international conventions setting out provisions for port facilities are in force except the ISPS Code, MARPOL or the Blue Code for the loading operations performed in bulk terminals (Fedi, 2008). To sum up, ports are not fully integrated and recognized throughout a universal legal framework, whereas they are nodal points of maritime supply chains engaged in greener policies (Bergqvist and Monios, 2019). More rules should already have been set out at a global level in order to ensure safety and environmental standards in ports. This justifies why an International Port Safety and Environmental Management Code has been developed by Bureau VERITAS, a French classification society, with the purpose of preventing injury or loss of life, and damage to environment through management systems (Chauvel, 2008). One can regret that such a regulation comparable to ISM Code for ships does not exist at IMO level since it would provide both a harmonized legal framework and avoid distortions of competition between ports (read 10484: Port Regulation).

Summary and Conclusion

Obviously, maritime regulation is facing more complex challenges at different scales. While the IMO affirms that "shipping is the most efficient, safe and environmentally friendly mode of transporting goods around the world", strong criticisms are addressed, and the IMO is now under severe environmental pressure (read 10479: The Future of Maritime Transport). That is not necessarily "black or white". The first challenge lies in the governance of regulation. We have underlined the flourishing of unilateral

legislations due to the IMO's slow pace. Finally, IMO continues to be seen as a "laggard" instead of a leader on environment. The IMO has to restore its slightly tarnished image and to reestablish its leadership. In 2016 the adoption of a Code of Ethics aiming to enhance the trust in, and the credibility of the IMO was a good sign in terms of independence, impartiality, integrity, and accountability of IMO personnel. Nevertheless, it is not enough. We are convinced that the IMO has to set up a radical change in its environmental policy if the Organization wishes to reaffirm its long-standing position while it requires a strategic shift. On the one hand, more ambitious policies are needed and concerning air pollution from ships above all. On the other hand, greater transparency and accountability are needed.

Today, more than ever, it belongs to IMO to regain—or not—leadership in maritime regulation. The EU has clearly shown the path forward for a more sustainable shipping in terms of safety or environmental protection and other countries will follow the same strategies especially as regards air pollution. The IMO Strategic Plan 2018-2023 demonstrates that the organization is aware of the main current challenges on efficient implementation of regulations, new technologies, and climate change while one regrets that is not its top priority. Then, the main strategic stake is obviously to turn words into tangible actions as of today.

Introduction

The categorization of ships into different types is not to be confused with the process of vessel classification in the maritime industry. Under the vessel classification process, classification societies, which are nongovernmental organizations, establish and maintain technical standards addressing the construction and maintenance of ships and offshore structures. Through the process, classification societies verify the design of a ship against established rules and international regulations with the overall objective of promoting maritime safety and environmental protection.

This chapter provides an overview of the classification process before exploring the main categories and subcategories of ships.

Marine Classification

The process of classification in maritime industry provides a means to verify the integrity of the structure and machinery including the propulsion, steering, and other essential components of a ship. Classification societies act as independent arbiters of standards, establishing rules and verifying compliance during the design, construction, and operational phases of a ship's life cycle. Classification societies also act as Recognized Organizations, performing statutory inspections for vessels on behalf of flag states. This role of classification has been recognized by the International Maritime Organization within the International Convention on the Safety of Life at Sea (SOLAS) and the International Convention on Load Lines (1988). The classification status of a ship has important implications on insurance coverage.

Today, more than 50 organizations provide ship classification services worldwide. Among them, 12 classification societies are part of the International Association of Classification Societies (IACS), which collectively classes 90% of the commercial tonnage in the world (iacs.org.uk).

Cargo Transportation

As technology evolves, modern ships, especially commercial ships, are designed to efficiently serve very specific purposes. The majority of maritime transport comprises cargo transportation—among which oil tankers and bulk dry cargo carriers are the main

Figure 1 Total number of vessels over 100 gross ton.

players. The world fleet is growing each year. In 2019, the total number of vessels over 100 gross ton in the world was exceeding 96,000¹ (ABS database) **Fig. 1**.

Vessels have evolved significantly over the years. Utilizing human power and wind to propel vessels, our ancestors left footprints all over the world traveling by ships. Ships were designed and built to carry passengers, transport cargo, and when needed were equipped with weapons for use in attacking others or for protection from pirates. In a way, the vessels could be considered as multipurpose. When global trade boomed in the 16th century, businesses began to experience a demand for a large amount of trading goods, marking the beginning of specialized vessels. Vessels carrying large quantities of rice, wheat, spices, barreled oil, and wine were in demand, with new designs optimized for maximum carrying capacity.

The invention of steam engines boosted transatlantic traffic in the 19th century. However, wooden-hulled vessels were no longer sustainable for the newly installed steam engines, especially traveling transatlantic. Iron hull and later steel hull vessels became the new standard, which allowed vessels to be built substantially larger (Sager, 1996).

Bulk Carrier

A bulk carrier or bulker generally is designed to carry dry cargo in bulk, such as ore, grain, or coal; it is one of the most popular vessel types in modern time. Bulk carriers come in a variety of sizes, measured in Deadweight Tons (DWT), which represents the sum of the weights of cargo, fuel, fresh water, ballast water, provisions, crew, and if applicable passengers that a ship can carry **Table 1**.

Although vessels can be built in any size and shape, for the purpose of maximizing the economic value, they are generally built based on the trading route. The Handysize and Handymax vessels are the most popular sizes for bulk carriers. Their convenient size lets them into almost any port and terminal in the world. Panamax and Suezmax are sizes of vessel with maximum length and draft to go through the Panama and Suez Canals. Post Panamax are vessels built to pass the newly expanded Panama Canal which was completed in 2016 (pancanal.com, 2019). Port Kamsar in the Republic of Guinea is known for exporting large deposits of bauxite, which is used for producing aluminum. The sole pier in Port Kamsar, however, has vessel length restriction of 229 m. Thus, a Kamsarmax vessel is usually a Panamax sized vessel with an overall length less or equal to 229 m. Capesize Vessels are too large for Panama and Suez Canals, they trip around the Cape Horn in South America or Cape of Good Hope in South Africa instead. Very Large Ore Carriers (VLOC) and Very Large Bulk Carriers (VLBC) are also restricted to only trade between these “Cape” terminals around the world **Fig. 2**.

¹The number accounted for propelled sea going merchant vessels in excess of 100 Gross Tonnage
The number accounted for propelled sea going merchant vessels in excess of 100 Gross Tonnage

Table 1 Categories of bulk carriers

	Category of bulk carrier
≥ 200 K	VLOC and VLBC
120–200 K	Capesize
83–120 K	Post Panamax
80–83 K	Kamsarmax
65–80 K	Panamax
40–65 K	Handymax
10–40 K	Handysize
< 10 K	Small bulker

VLBC, very large bulk carrier; VLOC, very large ore carrier.

**Figure 2** Bulk carrier.

Tanker

Originally, liquid products such as oil and wine were transported in containers, primarily barrels for easy offloading and subsequent transportation. In 1886, in Newcastle Upon Tyne, United Kingdom, the world's first oil tanker, *Gluckauf*, was built with cargo compartments to hold large quantities of oil instead of barrels (Nielsen, 1958). *Gluckauf* was designed with longitudinal and transverse bulkheads to subdivide the cargo space into eight oil tanks. By removing the need for barrels, more oil could be stored on the ship. Today, tankers are equipped with high- and low-pressure piping systems to facilitate the loading and offloading of the liquid cargo at port facilities Table 2 and Fig. 3.

Container Carrier

Container carriers are easily recognizable with their neatly stacked containers. The truck-sized intermodal containers are standardized to be either 20 feet (6 m) or 40 feet (12 m) long. As a result, the capacity of container carriers is measured in how many containers they can carry, known as twenty-foot equivalent unit (TEU) Table 3 and Fig. 4.

Today, container carriers are an integral part of the intermodal transport network. The containers can be seamlessly transported between truck, rail, and vessels with minimum disturbance to the cargo within. The container terminals at ports are equipped with large cranes to load and offload containers, allowing minimum turnover time.

Gas Carrier

Natural gas and petroleum gas have gained popularity in recent years as alternative energy sources to traditional coal and petroleum. These gases were once considered as wasted by-products of petroleum drilling and production until extraction and storage technologies developed. Natural gas is a hydrocarbon gas consisting predominately of methane. Petroleum gas has a more complex profile, often referred to as propane and butane isobutane, while it can be a mixture of these two along with other hydrocarbon gases. Since the gases have different chemical composition, they are separated during transportation to avoid contamination. Piping, gas storage, and venting arrangements along with loading and off loading operations need to follow established requirements to ensure there is no leakage of the gas into the atmosphere.

Table 2 Categories of tankers

<i>Vessel DWT</i>	<i>Category of tanker</i>
≥200 K	VLCC
125–200 K	Suezmax
85–125 K	Aframax

>15 K	ULCS
8–15 K	Neo-Panamax
3–8 K	Intermediate
<3 K	Feeder

ULCS, ultra large container ship.

Trading and transporting gas in a gaseous state can be difficult to justify economically. As a result, a liquefaction procedure is commonly used to change the gases into their liquid state, which can result in up to 600 times the volume being carried in the same space. Although gas liquefaction technology has been around since early 1900s, the first Liquefied Natural Gas (LNG) carrier was retrofitted in the late 1950s and traveled in 1964 for long-distance transportation (Tusiani and Shearer, 2007). The liquefied gases are stored in insulated cargo spaces with temperature and pressure control that is unique to their chemical characteristics. For example, natural gas needs to be cooled to approximately -162°C to remain in a liquid state. The loading and offloading piping system at the port terminal allows the gases to return to gaseous state and transported to local distribution networks. The capacity of gas carriers is measured in the volume (in cubic meter) of the liquified gas they carry **Table 4**.

General Cargo Carrier

General cargo carriers are designed to carry homogeneous or inhomogeneous general cargos that are manufactured and stored in any shape or form. General cargo carrier designs include single-deck, tween-deck, or triple-deck configurations. The tween-deck cargo carrier was a popular vessel type before the invention of the container carrier. The 9000 DWT tween-decker Liberty-type vessels, built in the United States during World War II, were used to transport a variety of war supplies. After World War II, Liberty vessels were

Figure 4 Container vessel.

Table 4 Categories of gas carriers

<i>Vessel capacity (cubic meters, cbm)</i>	<i>Category of gas carrier</i>
≥80 K	LNG—Large
<80 K	LNG—Small & medium
≥50 K	LPG—Large
22.5–50 K	LPG—Mid
<22.5 K	LPG—Small

bought by Greek ship owners and became prevalent in the maritime trading market. Other general cargo carriers were soon built following Liberty's success. A more modern multipurpose general cargo carrier design was added to this type that can carry regular or irregular shaped and sized cargo (Spirou, 2011).

Ro-Ro Carrier

Roll on/Roll off (Ro-Ro) carriers allow wheeled cargos such as vehicles or trains to roll from pier to the vessel through ramps and vice versa. This unique type of vessel can be tracked back to the 19th century when the Ro-Ro carriers were used to carry steam trains across the river; the Firth of Forth ferry in Scotland dated back to 1851 was an example of an early Ro-Ro carrier (Hilton, 2003). The functionality of Ro-Ro carrier expanded to carrying war vehicles such as tank during World War II, and subsequently commercial cargos after the war. Nowadays, Ro-Ro carriers often operate as ferries with passengers driving their vehicles on to the vessel and driving off when the vessel reaches port.

Passenger Transportation

While passenger transportation was traditionally one of the main functions of ships, its popularity declined in the 20th century for long transits, as air transportation became a more efficient means of transportation. However, ferries and cruise ships remain popular.

The International Maritime Organization (IMO) defines a vessel carrying more than 12 passengers as a passenger ship. When traveling on international voyages, these passenger ships must comply with relevant IMO regulations, including those in the SOLAS and Load Line Conventions. Safety measures incorporated into these requirements include emergency escape routes, life-saving appliances, and lifeboats.

Ocean Liner

Ocean liners were once the only transportation mode available for transoceanic travel, operating on a regular schedule of ports. In the early 20th century, many of the liners were able to travel between continents and were built with exceptional luxury, offering a range of passenger accommodations. Many of the ocean liners were retrofitted to troopships during World War II to transfer soldiers. *RMS Queen Mary* held the record of most passengers transported on one vessel with a total of 16,683 soldiers and crews (Miller and Miller, 2012). After the war, many of the surviving liners converted back to ocean liners and resumed transatlantic voyages. Later, some of the liners were converted to cruise ships upon the rise of air travel while others eventually retired. Today, the *RMS Queen Mary 2*, remains as the only ocean liner, traveling between Southampton, England and New York City, United States.

Figure 5 Cruise ship.

Cruise Ship

Modern cruise ships often have a capacity of multiple thousand passengers, providing a wide range of onboard entertainment, including fine dining, theater, and sports. Cruise ships are often designed with passenger cabin arrangements to maximize the number of ocean-viewing rooms with private verandas. Although speed was not originally a priority for cruise ships, recently more cruise ships are designed to travel at a high-speed range, comparable to the ocean liners, to serve more seasonal business around the world.

Special destination cruises are designed to travel in different sea conditions. Popular destinations include the tropical waters in the Caribbean. This route requires cruise ships to have a shallow draft that allows them to enter ports. Cruise ships visiting polar regions are referred to as polar cruises and are designed to meet the International Code for Ships Operating in Polar Waters by the IMO [Fig. 5](#).

Ferry

Ferries come in a variety of sizes and typically travel between designated ports over relatively short distances on a regular schedule with fixed fares. The route can be point to point or with multiple stops in between as a water taxi or bus. They can be an integral part of local public transportation, or offered as an entertainment service for tourism. Some of the larger ferries travel longer distance and offer overnight cabins for passengers; the accommodations on the ferries can be very similar to those found on cruise ships.

There are many different designs of ferries offering diverse functionalities for passengers and their cargos. One of the most common types is the catamaran, a high-speed ferry that typically carries passengers only. Catamarans have a distinctive twin-hull design with very slender hull forms. The hull surface in contact with water is reduced in this design and thus has less drag resistance, allowing the catamaran to operate more efficiently at a high-speed range. Another unique design of ferries is the double-ended ferry. This type of ferry does not need to turn around at port because it has the same propulsion capability when operating in either direction.

Yacht

Though once used to pursue pirates by the Dutch Republic Navy ([Clark, 2015](#)), yachts today are mostly used for leisure in forms of racing and cruising. A yacht hull can be constructed with steel, fiberglass-reinforced plastic (FRP), or aluminum; the latter two are lighter in weight and are especially suitable for large yachts. The propulsion for modern yachts typically comes from internal combustion engines while sails are often installed as well. While typically monohull, yachts can also have twin or triple hulls for high-speed options, similar to a catamaran.

Service Vessels

Besides the vessels mentioned above, there are many other types of vessels, which exist to serve various purposes. These include service vessels such as tugboats and towing vessels, icebreakers in polar regions, industrial fishing vessels, research vessels, and service vessels to the oil and gas industry. Some of them are designed to carry passengers and special cargos while their range of activity is usually limited to certain regions depending on their service application.

Figure 6 Floating production storage and offloading unit (FPSO).

Vessels such as *tugboats* and *towing vessels* usually work close to harbors or inland waterways to provide assistance to larger vessels by providing additional propulsion power and maneuverability. Tugboats are often small in size but equipped with high power engines and strong hulls. They can help large vessels in narrow and busy ports or maneuver immobile craft such as disabled ships, barges, or oil platforms. Towing vessels function similar as tugboats, being used for emergency towing for disabled vessels and maneuvering large loads.

Icebreakers are specifically designed to travel through polar regions to break ice layers without damaging their hull. Such ships are designed to specific regulations, including the International Code for Ships Operating in Polar Waters, with a stronger and thicker hull and a sloping bow profile to cut through ice.

Fishing vessels can be found operating in lakes, rivers, or deep sea. Industrial fishing vessels are commercially operated to catch large quantities of fish and other seafood. A trawler is a popular type of fishing vessel that uses a trawl net to catch seafood. They often have large refrigerated cargo spaces to store the catch. Factory vessels can also be part of a fishing fleet, providing services to clean, process, and store seafood before transporting it to land to sell. Smaller privately owned fishing vessels can be considered supplemental, serving local or regional markets.

Research vessels are designed for exploration and data collection. There are many different types of research they can conduct, including oceanographic surveys, hydrographic surveys, polar research, and other industrial research such as fisheries and oil exploration.

Ships are also engaged in offshore and gas exploration and production. While some offshore installations are fixed platforms installed at one location for their service life, others are ship-shaped vessels used in mobile or semimobile forms.

Drillships are used for exploratory drilling. Such vessels typically have a moonpool opening in the middle of the vessel through which drilling operations into the subsea structure can be completed. Dynamic positioning systems installed on the vessels allow the vessel to remain at a fixed location, countering the impact of wind, waves, and current while the drilling operations are completed.

Ship-shaped Floating Production, Storage and Offloading (FPSO) vessels are another type of vessel used in offshore applications. These vessels, which are typically permanently moored, process the oil from the well, separating the oil and gas, storing the product onboard before offloading to a shuttle tanker **Fig. 6**.

Military Ships

Military ships include navy, coast guard, and constabulary vessels, and may be both combatants and noncombatants. They serve very different purposes compared to commercial or civilian ships and are typically national government assets. In many cases—particularly navy and coast guard ships—they are designed to go in harm's way; this could be for both coastal defense and combat roles with an aggressor's naval forces, as well as power projection in action far from the home nation. Consequently, these ships are typically designed to different requirements with much higher standards of structural, mechanical, and electrical integrity and redundancy, with greater focus on damage control and survivability in the event of an incident.

"Survivability" is a critical consideration for a military ship. For commercial vessels, this entails the ability to withstand loads due to inclement environments and operate even if critical components or systems fail. Military ships have the additional burden of surviving in combat environments. Both offensive and defensive measures can be taken to improve the survivability of the vessel. Survivability for naval vessels is composed of four basic properties:

Susceptibility: This is principally a ship's ability to avoid detection from other offensive ships, which depends greatly on its signature. Each naval ship has unique signature characteristics in various regions of the electromagnetic spectrum. The spectrums most commonly used for identification and detection purposes are visual, microwave, and infrared. Reducing or modifying the various signatures such that they match the operating environment can enhance the survivability of the vessel. Of course, sound and visual identification remain equally important to signature.

Figure 7 French Navy Aquitaine-class FREMM multipurpose frigate FS Provence (D652).

Figure 8 The United Kingdom's Royal Navy aircraft carrier *HMS Queen Elizabeth* (RO 8) (The Queen Elizabeth-class aircraft carrier HMS Queen Elizabeth (RO 8) sails the Atlantic Ocean).

Vulnerability: The ship's ability to continue to conduct its mission, either fully or partially, and to protect its crew, after an offensive weapon has struck the ship. The design is to attempt to minimize damage as best as practicable; this can either be done through thwarting the ability of an enemy to successfully acquire targets on the ship (such as through electronic countermeasures, or even through design by providing protected accesses for crew transit onboard the ship to minimize open air movement); providing means to reduce the energy of the weapon effect (such as through the use of outer tanks to avoid penetration into vital ship spaces); or structural hardening to prevent weapon penetration into the ship's hull or superstructure.

Recoverability: The ability of a ship to quickly recover post enemy engagement; this could be either to withdraw from engagement and seek sheltered waters, or to continue to engage the enemy while engaged in casualty repair (through either active damage control measures or via inherent system redundancies).

Lethality: This is the ability of a ship to successfully engage an enemy using its offensive weapons or other assets such as aircraft, helicopters, or unmanned underwater, surface, or aerial vehicles. This is typically considered the prime mission of military ships **Fig. 7.**

The modern navy fleet can be divided into two major groups: (1) Combatants and (2) Auxiliaries, such as Repair, Scientific Support, and Supply and Transport (also referred to as Sealift) vessels. The combatant vessels make up the battle fleet, with each vessel designated a specific role for military and combat operations. In lower intensity conflict operations, such as antipiracy or coastal patrol operations, some combatant vessels can and are expected to operate on solo missions, such as medium endurance patrol ships or offshore patrol vessels (OPV); some highly capable military ships may work alone in significant conflict environments such as the destroyer or frigate type ship. However, in most cases, navy ships are designed to operate as part of a larger task force or battle group; for those with helicopter carriers or aircraft carriers, these are sometimes referred to as carrier groups. Typical combatant ship types found in navies range from relatively small armored gunboats, minesweepers, and missile patrol boats to medium-sized offshore patrol vessels, corvettes, and frigates; to larger destroyers and cruisers; and finally to the largest classes of multirole capital ships referred to as helicopter carriers, amphibious warfare vessels, and aircraft carriers **Fig. 8.**

In addition to the combatant vessels, auxiliary support vessels are used to perform a vast array of fleet support functions such as repair (ship and submarine tenders), resupply (stores ships, ammunition carriers, and tankers known as "oilers"), transport (amphibious support vessels or sealift ships), and special mission ships. Special mission ships can incorporate a large variety of

Figure 9 United States Navy dry cargo ship *USNS Robert E. Peary* (Lewis and Clark-class dry cargo ship *USNS Robert E. Peary* (T-AKE 5) transits the Atlantic Ocean after successfully conducting a replenishment-at-sea).

vessels such as for oceanographic survey and mapping, electronic and oceanographic surveillance, and hospital and medical services. The auxiliary fleet provides vital logistics and support to the combatant force and has the added capability in many navies of resupplying a task force while underway, referred to as underway replenishment **Fig. 9**.

Summary and Conclusion

The maritime industry is made of vastly diverse ship types that are designed to perform different and specific tasks. Most of the transportation ship types are dictated by the cargo they intend to carry, may it be passengers, dry or wet cargo. Classification societies continuously serve an integral role in the industry as a third-party verification with the state-of-the-art development to ensure the safety standards for these ships.

Biographies

Dr. Gareth Burton is Vice President Technology in ABS (American Bureau of Shipping). He began his career with a consulting engineering company before joining ABS in 2001. During his time with the organization, he has held various roles in engineering, business management, and product development in the United States, Mexico, and Singapore. In his current role, he is responsible for the development and execution of the ABS research program.

Gareth holds a Bachelor's Degree from the University of Manchester, England and a Master's and Doctorate of Engineering from the University of Ulster, Belfast, Northern Ireland. In addition, he has completed the Executive MBA program through Texas A&M University.

Mimosa Miller is an engineer in ABS (American Bureau of Shipping). She began her career in 2016 in the "Aspire" rotational program and engaged various activities in different departments. Currently, she is part of the Technology department in Houston, and her fields include structural analysis, hydrodynamic analysis and emission control. Mimosa holds a Bachelor's Degree for Civil Engineering from the Cooper Union for the Advancement of Science and Art in New York, United States and a Master's Degree for Ocean Engineering from Texas A&M University.

Introduction

The function of the shipbuilding industry in the context of maritime transport is rather obvious—it creates the shipping capacity that moves seaborne trade. How it does, is a question of engineering and industry, and is of limited relevance in an encyclopedia of transport. Of more significant interest in this context is an exploration of how the shipbuilding and shipping sectors interact and this is the focus of the following chapter.

The mandatory use of classification societies in assuring the quality of new ships (IMO's SOLAS convention dictates that a ship cannot trade without a valid Cargo Ship Safety Construction Certificate) means that there is limited room for shipbuilders to differentiate themselves from competitors on the basis of product quality or features. From the ship owners' perspective, therefore, the significant questions relating to shipbuilding are fundamentally limited to: where am I likely to order a new ship; how much will it cost and; how long will it take to deliver?

Further to this, shipping and shipbuilding are both highly cyclical and the interaction of the cycles tends to be periodically antagonistic. There are two fundamental problem periods. In the trough phase of the shipping cycle the shipping industry generates too low demand to utilize shipyard capacity, with resulting low prices, bankruptcies of shipyards, and the use of government subsidy to keep some suppliers afloat. Conversely, at the peak of the cycle, the shipbuilding industry has a tendency to oversupply shipping tonnage at a high price, due to overinvestment in new ships, with resulting overcapacity in the fleet and low freight rates. For reasons that will be postulated later, the nature of the industry is to oversupply and this leads to cyclical troughs in shipping that are both longer and deeper than they would need to be if overinvestment and overproduction could be avoided (Oecd, 2019; Stott, 2018a).

These matters are explored by reviewing the following fundamentals that form the structure of this article:

1. Development of demand and cycles
2. Development of competition and competitors
3. Development of backlog and price
4. Interaction between shipping and shipbuilding cycles

Demand and Cycles

Output of commercial shipbuilding between 1890 and 2018 is presented in Fig. 1, showing gross tons (GT) of shipping delivered.

The first significant feature of this time series that might be noticed is four significant peaks of output that can be seen in 1919, 1943, 1975, and 2011. The average period between peaks has been 30.6 years, but with the pitch of the cycle increasing over time: 24 years in the period to 1943, 32 years up to 1975, and 36 years for the most recent cycle that peaked around 2011.

The second feature that might be noticed is the exponential increase in the scale of the industry in particular in the era of globalization following WWII. Fig. 2 shows output in the peak years and its exponential development.

Figure 1 Global output of commercial shipping in Gross Tons (GT). WWII figures are difficult to obtain, with information on output from 'axis powers' in particular being scarce. The figures for the period 1939–44 are therefore estimates. *Source: Compiled from various archive sources available at the Marine Technology Special Collection, Newcastle University.*

Figure 2 The exponential development of peak outputs.

Figure 3 Peak shipbuilding output (GT) as a percentage of total fleet tonnage extant at the time. *Source: Compiled from various archive sources available at the Marine Technology Special Collection, Newcastle University.*

Each peak is exponentially larger than the preceding one and this has a tendency to “mask” the significance of previous peak values. Earlier peaks were equally significant at their time, however, as demonstrated by benchmarking the peak values against the total tonnage operating in the fleet at the time of the peak, as illustrated in Fig. 3.

The first two peaks of the 20th century were more significant, at 14% and 19% of total fleet tonnage, probably due to uplift from production to replace war losses. The latter two peaks were remarkably similar at 11% of fleet size. The significance of these statistics is that while past peaks look relatively small in retrospect, they would have been experienced as relatively similar in terms of size at the time they happened.

Figure 4 The appearance of market growth in the 25 years leading to peak levels.

Such an exponential increase in output would be anticipated in response to the exponential increase in seaborne trade that has also occurred in the period examined: quite simply, more trade requires more ships. What may not be anticipated, however, is the highly cyclical nature of this output and the extent of the dramatic and sudden fall in demand following the peak years—no such dramatic cycles are seen in the development of the seaborne trade that ultimately drives the demand for merchant ships.

Historical evidence reveals that this pattern of boom and bust long pre-dates the time series presented here, going back to at least the 18th century. There is clearly much more going on here than a rational investment in shipping tonnage to carry seaborne trade. In fact, demand for new ships is created at least in part by the demand to invest capital in shipping tonnage, rather than purely demand to fulfill the needs of world trade. This recognizes that the ship itself, possibly uniquely as a means of production, is a tradable commodity whose value rises and falls, presenting the opportunity for investors to make significant gains in what shipowners term “trading in steel,” that is to say the buying and selling of ships (Thanopoulou, 2002). Speculation and overinvestment are key drivers of the exaggeration of the shipbuilding cycles.

One final aspect of the pattern of output shown in Fig. 1 that is worthy of note is the consequence of the lengthening cycle in the postwar period and how the market would have looked to investors at the time these peaks were occurring. Fig. 4 shows how demand development would have looked to investors in the early 1970s and in the early 2000s.

Extended periods of almost unbroken strong market growth in shipbuilding in these two periods may have given the illusion that the underlying pattern of boom and bust in shipbuilding had not only disappeared but also that shipbuilding presented a reliable high-growth prospect for investment, with significant booms in shipyard construction accompanying these periods. The length of the cycles therefore carries with it something of a risk. The average of 30 years is of the order of magnitude of the length of a career and undoubtedly the senior management that had experienced the previous peak would predominantly have retired by the time the next peak manifests. Lack of memory in the system is therefore a concern and previous errors are prone to be repeated in future cycles.

Competition and Competitors

As with the development of demand, the availability of long time series enables trends to be identified that have a significant effect on the market. Fig. 5 shows the development of share of the market leader in global commercial shipbuilding in the period between 1892 and 2018 (Stott, 2018b).

It is easy to see from Fig. 5 why some commentators have tended to characterize competition in shipbuilding as a hegemony (Bruno and Tenold, 2011), that is to say dominated by a major supplier, with the market lead moving from United Kingdom to Japan following WWII, to South Korea in the 1990s and most recently to China. In the true sense, however, hegemony is probably an appropriate label only for United Kingdom in the late 19th century, with a peak of 82% market share in 1892. A noticeable trend in Fig. 5 is that the ultimate share achieved by each successive leader has reduced over time and that the period for which dominance has been maintained has also reduced with each leader: 50 years for United Kingdom, 40 years for Japan, but only 10 years for South Korea before China challenged the supremacy. Most recently, the three leading suppliers have seen something of a convergence of shares, rather than perpetuation of dominance, as was the pattern in the 20th century.

It is also relatively common for commentators to speculate where the dominating lead will move next, with both Vietnam and India, for example, having been mentioned as possible successors to China. Objectively, however, there is no reason to conclude that the pattern of “shifting hegemony” will propagate into the future and both these countries have not successfully pursued a market lead, at least so far. Barriers to success include very high capital cost and high risk of that capital in the face of the extreme market cycles previously described (Bruno and Tenold conclude that it is unlikely to be possible to establish a modern large scale industry without very significant government financial help). On the other hand, shipbuilding has proven to be a strong economic generator

Figure 5 Development of share of market leaders between 1892 and 2018. Source: Compiled from various archive sources available at the Marine Technology Special Collection, Newcastle University.

in the development of all three post-WWII leaders and, probably, in United Kingdom that preceded them. Japan specifically chose shipbuilding, among other industries, as part of the vehicle for re-building of its decimated economy post-WWII, leading eventually to Japan's "economic miracle" of the 1960s. Shipbuilding's strong economic multiplier, requiring skills and supply chain industries, was subsequently used strategically in South Korea to help to progress that country from an agrarian to an industrial economy (commencing with the construction of the Hyundai Heavy Industries Ulsan shipyard in 1973) and shipbuilding has subsequently played a similar role in China's economic emergence (Stott, 2017a).

The analysis of market share alone is to some degree misleading because it masks the effects of the exponential expansion in demand discussed in the previous section and a more nuanced view of competition is obtained if the time series is represented as tonnage delivered, rather than share. This is presented in Fig. 6.

The United Kingdom's extreme dominance in the late 19th century can be seen to have been dominance of a different historic industry to that which developed post-WWII in the era of globalization. United Kingdom's typical output of around 1 million GT per annum has been dwarfed by successors. WWII was a watershed for the shipbuilding industry, which almost changed beyond recognition in the postwar period. Not only the scale of the industry and its products changed but the processes and methods also changed, moving from riveting and erection of the ship piece by piece on a slipway, to welding and construction of prefabricated

Figure 6 Tonnage delivered by market leaders.

blocks, propagating the technologies and methods developed in the United States “emergency shipyards” during the war period, to mass produce “Liberty Ships” and “T2 Tankers.” The United States seeded this technology into Japan along with capital for shipyard development and that industry set the pattern for the industries that followed.

What has also changed is the way that shipbuilders seek to gain competitive advantage, with economy of scale having become the predominant mode in recent decades. Both United Kingdom and Japan achieved competitive dominance through technical leadership and the availability of strong home markets. South Korea, on the other hand, not having the benefit of the strong home market, has focused on competitiveness through economy of scale, which in turn has been facilitated by the exponential expansion of demand. The use of economy of scale in shipbuilding relates not only to the shipyard itself but also to the supply chain, bearing in mind that typically around 70% of the cost of construction of a merchant ship is constituted by steel and equipment purchased for fabrication and assembly. The factors of competitiveness developed by South Korea include strong domestic steel and equipment supply industries and the use of shipbuilding contracts that direct material purchases to those suppliers, giving buyers very little choice. A shipbuilding contract typically includes an attachment normally termed the “makers list,” which details the manufacturer of the main equipment items, such as main engine, generators, pumps, and so on. In Korean shipbuilding, the list directs the equipment purchases to domestic companies with established places in the supply chain, minimizing equipment cost through volume of purchases and by minimizing delivery and transaction costs. Control of the makers list is therefore a key to making economy of scale work in shipbuilding. To give an idea of the scale of volume achieved, the leading South Korean shipyards, at the peak of 2011, were fabricating around three million tones of steel per annum each, and purchasing, for example, around 80 main engines each per annum. Such volumes lead to significant economic advantages through sheer buying power and the incentive to set up supplier industries as close as possible to the shipyard. On the other hand, the supply chain suffers with the shipyards in periodic downturns, multiplying the economic problems that result (Stott, 2017b).

The level of scale in shipbuilding can be judged by reviewing the output of market leaders at the start of each decade over the past 60 years, as shown in Fig. 7.

It can be seen that the market leading shipyard in 2010 produced over thirty times as much tonnage and almost seven times as many ships as the market leader in 1960, with scale particularly taking off since 1990 as South Korea assumed the market lead. As a consequence of the pursuit of scale, the shipbuilding industry has become increasingly concentrated. In 2018, one quarter of the total commercial shipbuilding orderbook, measured by work content, was found in just five shipyards and one third in the leading ten shipyards.

China’s place at the top of shipbuilding’s “hegemony” is still playing out at the time of writing this article. China has the advantage that United Kingdom and Japan had before it, with a significant home market. Beyond that the pursuit of competitiveness through economy of scale and the development of ultra-large “mega yards” has to be questioned. The strategy works perfectly at the peaks but as seen earlier, the shipbuilding market is highly cyclical and the effectiveness of scale is reduced as utilization of capital investment, human capital, and the supply chain reduces rapidly in the downturns that have tended to follow the peaks. A significant question, therefore, is to ask whether shipbuilding can find a new operating model to move the industry on from the pattern of boom and bust, and the intermittent dependency on government subsidy that currently characterize it and that may be an inevitable consequence of the pursuit of scale and the development of “mega-yards.” There has to be a better way!

Figure 7 Output from the market leading shipyard at the start of each decade since 1960.

Price and Backlog

The economics of shipbuilding are substantially under-researched, with the profession of maritime economics concentrating primarily on shipping, trade, and port economics. It may come as a surprise, therefore, to learn that the definition of the global shipbuilding market in economic terms has not yet been achieved and the boundaries of the market and the econometrics of price formation remain elusive (Oecd, 2019).

From a pragmatic perspective it has long been assumed by those working in the industry that a single market exists, with prices determined by forces of supply and demand that are common across all ship types that compete for the same units of capacity. This is reflected in reality by a remarkable coincidence of price movement across almost all ship types over time. This tendency was first noticed a century ago (Ballard, 1921) and more recent studies have confirmed the parallel movement of prices of different ship types over time (Wijnolst and Wergeland, 2009). This pattern of behavior suggests that different ship types are part of the same market and that, from the perspective of the shipbuilder, the main ship types (tankers, dry bulk, and container ships) are substitutes in competing for available capacity. Shipyard capacity is broadly flexible across most ship types within the appropriate size range, with few exceptions. The exceptions are principally LNG tankers, for which technical, capital investment, and regulatory barriers to entry may exist, and passenger ships, for which technical, capital investment, supply chain, and customer factor barriers may exist.

The strong correlation of prices gives validity to the use of composite indices as a proxy for evaluating ship prices. The derivation of such an index over the long term is difficult due to shifts in ship types involved in world trade and because prior to the most recent period data on ship prices was relatively scarce. The most commonly used index is that of Clarkson research, presented in Fig. 8, covering the period of the most recent shipbuilding cycle.

Probably, the most striking feature of this graph is the extent of fluctuation of prices. The price of a VLCC, for example, rose from \$64 million in the beginning of 2003 to the peak at \$162 million 5 years later in 2008, only to fall back again to below \$100 million by 2010. The opportunity to make significant sums on the speculative purchase of ships is clear from this example, as is the opportunity to lose significant sums with poorly timed investments.

Research has generally concluded that there are two primary determinants of newbuilding price: the rational value of the ship to the buyer based on their expected earnings through freight, in other words what the buyer can afford to pay, and the cost of construction, or the minimum price a yard could accept without making a loss (Dikos, 2004; Haralambides et al., 2005; Jiang and Lauridsen, 2012). The relative influence of these factors appears to shift over the cycle, with rational value predominating in strong (sellers') markets and cost of construction predominating in weak (buyers') markets.

A significant predictor of price is backlog, that is to say the period between placing an order and receiving a ship (Oecd, 2019). The development of backlog (measured in years) over the most recent cycle is presented in Fig. 9. It can be seen that at the peak of the market in 2008, backlog was approaching 6 years, presenting a significant risk for buyers and a very comfortable forward workload for builders.

Backlog is of significance to both the buyer and the builder of a new ship. For the buyer, it represents scarcity of capacity and introduces an element of risk into the purchase: what will shipping market conditions be like when the vessel is delivered? For the builder, it represents scarcity of orders and ultimately the time up to the point when the shipyard will run out of work if no more contracts are won. It is calculated by dividing the current orderbook by the rate of production over the past year, with rate of production providing a proxy for active capacity in commercial shipbuilding.

The strong relationship between backlog and price is illustrated in Fig. 10, where the two factors are plotted together.

Two conclusions in particular have been drawn from the analysis of capacity and price. First, buyers become more price sensitive once the backlog exceeds about 4 years, becoming resistant to further price rises even if demand continues to increase. Second, backlog tends to stay above about 2 years, being a minimum level for confidence in the shipyard that it is not running out of work.

Figure 8 Clarkson Research Newbuilding Price Index.

Figure 9 Development of backlog over the most recent cycle.

Figure 10 Backlog and price plotted together in the most recent cycle.

The Interrelation Between Shipping and Shipbuilding Cycles

Freight rates in commercial shipbuilding are determined by the interrelation between supply and demand, supply being the capacity of the fleet and demand being the volume of seaborne trade that needs to be moved to keep the global economy functioning. The economics of the supply and demand functions, particularly for bulk trades, are well established in the literature of maritime economics and the shapes of the functions tend to promote a particular pattern of freight rate development (Stopford, 2009). For most of the time the shipping markets function at relatively low freight rate levels, with an overcapacity of ships looking for cargoes. Periodically a balance is achieved, however, and at that point freight rates tend to rise spectacularly and make shipping a highly attractive business. Demand continues to grow as world trade expands but the backlog means that it takes shipbuilding some years to expand the fleet and a shortage of tonnage results. The resulting pattern is illustrated in Fig. 11, showing average daily earnings for a capsize dry bulk carrier (a bulk carrier of about 170,000 dwt that typically carries iron ore or coal).

It can be seen that earnings fluctuated around \$15,000–\$20,000 per day between 1990 and 2003, and had been at that level for most of the 1980s since the collapse of the previous boom. In 2004, however, the market picked up and rates rose to around \$90,000 per day and then in 2007/8 up to stratospheric levels of \$190,000 per day. At these rates, bulk shipping becomes highly profitable and investors and capital providers become very interested in the prospects of shipping. It had been 30 years since such conditions had been last seen and the memory in the system was insufficient to engender any caution in the lending of money and placing of orders to participate in this boom market.

What had happened was that, with freight rates persisting at a low level for so long, investment in new ships had not been sufficient to keep up with the expansion of trade and the fleet surplus generated by the previous peak in the 1970s was eventually eliminated, with the consequent upswing in freight rates. The rate of investment in ships that followed was far beyond that needed to sustain trade growth, however, and by 2008 it had become clear that the fleet was being overinvested and the adverse balance was being re-established. At that point, freight rates plummeted back to their long-term low point, this time well below \$20,000 per day, but backlog had grown to almost 6 years. In other words, there are no brakes in the system. Once it has been realized that

Figure 11 Average capesize long run historical earnings. *Source: Clarkson Research.*

overcapacity has become a problem, it took another 4–5 years before volume orders of new ships stopped flooding into the market. The result is that shipping switches back to the trough phase. The capital providers and investors exit the industry, which by this time has developed a poor reputation for investment, and the fleet will then proceed through another extended period whilst the expansion of world trade absorbs the overcapacity that has been created. At which point, the vicious cycle will reassert itself, unless we learn the lessons and try to find a way to stop this damaging pattern.

For those that know how to play the system, the exaggeration of the shipping and shipbuilding cycles is an opportunity to make large amounts of money in a short period. Over the long term, however, few really win. Shipyard capacity is left without sufficient orders and yards face either closure or the need for subsidy and shipping capacity is left facing a long period of suppressed freight rates and difficult business conditions.

It is both unlikely and undesirable that the cycles in these systems could be eliminated. What might be eliminated, however, is the damaging exaggeration of the cycles, rendering the businesses on a more sustainable footing. Part of the solution is to introduce memory into the system, we have enough time series now to understand what is happening. It might also be possible to introduce a leading indicator, to warn inexperienced capital when the rate of inflow of money is exceeding the rational demand for new ships that seaborne trade can sustain.

Introduction

For a public transport system to be successful, the network must be designed properly. Like any other system, the users of the system define the attributes that characterize, in their view, a good system. In the case of public transport, the users are the passengers. According to Walker (2012), there are seven broad expectations from passengers: (1) spatial accessibility, (2) temporal accessibility, (3) speed, (4) affordability, (5) safety and comfort, (6) reliability, and (7) simplicity. These seven expectations can be assigned to different planning levels when designing a public transport system. As identified by Ceder and Wilson (1986), there are three levels of planning: strategic, tactical, and operational. While spatial and temporal accessibility are covered in strategic and tactical planning, reliability, safety, and comfort fall under operational planning.

Since the focus of this chapter is network design, only strategic planning will be covered. This includes network design, frequency setting, and holistic evaluation of the designed network. Still, other passenger expectations are important and merit consideration. There is a common belief that if the strategic planning is done properly, other expectations are much easier to manage. Public transport network design involves creating a set of routes and their frequencies by incorporating objectives such as minimization of passenger costs or minimization of operator costs. These objectives are subjected to a number of different constraints, such as fleet size and unsatisfied demand percentage. Formally, it is known as the transport network design problem (TNDP) and if frequency setting problem is also involved then TNDFSP.

When considering the interests of both operators and passengers, it is quite clear that many of these are in conflict with each other. Adhering to the interests of one party is likely to lead to an unrealistic network for the other. In order to have a realistic public transport network that provides a suitable balance between passenger and operator viewpoints, transport authorities must play a role. They can do this by setting service-standard levels and policy guidelines.

While most public transport networks have evolved over the past few decades, the networks themselves have become more and more redundant and in some cases extremely inefficient. Therefore, restructuring or realignment of such networks is necessary for network improvement. There are different approaches to designing public transport networks. According to Kepaptsoglou and Karlaftis (2009), these approaches can be categorized into two major classes: conventional and heuristics. Conventional methods include the analytical models and mathematical programming formulations, whereas the heuristic approaches include heuristic and metaheuristic algorithms.

This chapter is structured as follows: first section will begin by presenting the literature review, which includes different approaches to tackling TNDP/TNDFSP. In second section, a novel approach will be used to explain how different types of public transport networks can be created, how demand is assigned, and finally how to holistically evaluate the public transport network. Finally, in third section we offer comments on how public transport authorities in North America have dealt with network redesigns and how an algorithmic approach can benefit public transport authorities to design better networks.

Literature Review

There are two main approaches to solving TNDFSP, namely heuristic and exact methods. Heuristics are the simplest procedures used in a systematic way to solve the TNDFSP. Occasionally, heuristics are used along with metaheuristic methods (stochastic optimization algorithms) to solve TNDFSP. These models are not problem specific and are extremely flexible, making it easy to adopt for any objective and constraint. In exact methods, the TNDFSP needs to be formulated into known mathematical models. Such models can find the optimal solution, but they are less flexible and can only be implemented on generalized small networks.

Heuristic and Metaheuristic Approaches

The use of heuristic and metaheuristic techniques are the most common types of approaches used in solving the TNDFSP; they are widespread and have been used in public transport design for many years. The basic versions are mostly domain specific and depend upon the knowledge and experience of public transport planners. In contrast, more advanced versions—called metaheuristics—do not require such knowledge.

Mandl (1980) use a rule-based heuristics to derive optimal routes with fixed headways. Ceder and Wilson (1986) adopt two-level approach for bus route network design and the frequencies. Baaj and Mahmassani (1991, 1995) propose an artificial intelligence-based approach to solve the TNDFSP problem. Carrese and Gori (2002) propose a hierarchical urban transport-network design methodology, composed of express and feeder routes. Lee and Vuchic (2005) use an iterative approach to solve the TNDFSP with varied demand. Fan and Mumford (2008) propose a metaheuristic-based approach for solving the TNDP. Bagloee and Ceder (2011) propose a hierarchical network-design methodology for actual-size networks. This include categorization of stops, manipulated shortest-path algorithm and metaheuristics.

Szeto and Wu (2011) use genetic algorithm (GA) and neighborhood-search heuristics to solve TNDFSP. Nayeem et al. (2014) use a greedy algorithm and GA with elitism to solve TNDP. Kiliç and Gök (2014) employ heuristics, hill climbing and tabu search to solve TNDFSP. Arbex and da Cunha (2015) use heuristics and alternating objective GA to find the best public transport network. Kim et al. (2016) solve the TNDP, by simultaneously deciding the mode type, route configuration, and its frequency. Huang et al. (2018) introduce a three-stage method to solve TNDFSP, including network hubs identification, route creation and optimization.

Exact Method Approaches

The mathematical approaches for the TNDFSP (TNDP + TNFSP) tend to focus on specific aspects of the problem, mainly due to its NP-hard nature and their tendency to get more inefficient as the problem instance grows.

Furth and Wilson (1981) propose a model to solve the problem of bus allocation to the public transport routes to maximize net social benefits. Constantin and Florian (1995) formulate a bi-level min-min problem to optimize the route frequencies, with the main objective being minimizing the total travel time. Bussieck (1998) solve the TNDP via relaxation and the branch-and-bound method. Wan and Lo (2003) solve the TNDFSP by modifying the existing transport system with the objective of minimizing the sum of the operating costs. Guan et al. (2006) solve the TNDP by a standard branch-and-bound method. Cancela et al. (2015) formulate TNDFSP as mixed-integer linear programming (MILP) formulation with the objective of minimizing passenger costs while adhering to the limited fleet-size constraint. Chu (2018) proposes an innovative mixed-integer programming (MIP) model to solve TNDFSP for minimizing sum of operating cost, passenger cost and unsatisfied demand.

The ability of exact methods to find the optimal solution makes it an obvious choice in many domains. However, in TNDP and TNDFSP, these methods do not scale well to actual-sized public transport networks. Most of the mathematical models are tested either on small test networks or simplified real transport networks.

Typical Methodological Procedures

According to Kepaptsoglou and Karlaftis (2009), the methodological procedures used to solve TNDFSP via heuristic and metaheuristic approaches can be grouped into four general categories: (1) route creation, (2) route selection, (3) route configuration, and (4) network improvement. Different approaches, methodologies, and procedures are used to solve TNDP/TNDFSP. To provide an overview and summarize the key features, selected studies are classified according to eight features, listed in Table 1. For the sake of simplicity and organization of the information, the following terms are used in Table 1:

AB	Available budget
AON	All or nothing
BM	Benchmark
CAM	Custom assignment model
CCHWAM	Capacity-constrained headway-based assignment model
CDAM	Combined-distribution assignment model
DS	Demand satisfaction
DS 0/1/2	Demand satisfaction through 0, 1, 2 transfers
DT	Direct trips

FIC	Fictitious
FS	Fleet size
H	Heuristics
HWAM	Headway-based assignment model
LF	Load factor
M	Mathematical
MH	Metaheuristics
ND	Network directness
NI	Network improvement
NoR	Number of routes
NoS	Number of stops
NoT	Number of transfers
OC	Operator cost
P&OC	Passenger and operator cost
PAM	Probabilistic assignment model
PC	Passenger cost
PD	Path deviation
RBT	Route backtracking
RC	Route creation
RCO	Route configuration
RE	Route efficiency
RH	Route headway
RL	Route length
RS	Route set
RSL	Route selection
RsC	Route set connectivity
SPAM	Shortest path-based assignment model
TNL	Total network length
TTT	Total travel time
USD	Unsatisfied demand
VC	Vehicle capacity
WT	Waiting time

Limitations of Existing Methodologies

Extensive literature is available on TNDFSP, and a number of reviews—such as those done by [Farahani et al. \(2013\)](#), [Guihaire and Hao \(2008\)](#), [Ibarra-Rojas et al. \(2015\)](#), [Kepaptsoglou and Karlaftis \(2009\)](#), and [Schöbel \(2012\)](#)—have been done in recent years. These reviews discuss the methodology type, inputs, outputs, constraints, and general aspects of the TNDFSP. Although they summarize different aspects of TNDFSP, none of them discuss the quality of results produced by these methodologies. More recently, [Ul Abedin et al. \(2018\)](#) conducted a study on the evaluation of the solution quality of the 27 studies. They performed the evaluation by creating a quality-evaluation platform that enables a comparison of their solution qualities. It revealed the following:

- The proposed solutions could perform according to their specific objective functions for smaller networks, but failed to show the same quality for larger networks.
- The quality of the solutions was not consistent with the variation in the network size and other inputs.
- Realistic demand assignment procedures should be used instead of simple procedures.
- Mode type should be considered as an integral part of TNDFSP, especially for large networks.
- For smaller networks, there were many comprehensive solutions, meaning that they performed well on all related indicators, but for larger networks, only a few solutions showed partial comprehensiveness.

A Novel Route Overlap-Based Approach to Solving TNDFSP

A novel heuristic approach is proposed to showcase how the TNDFSP can be solved and to design a network that is acceptable to relevant stakeholders, including passengers, operators, and authorities. The developed methodology includes three major components: (1) route and network creation; (2) demand assignment; (3) network evaluation. For network optimization, such approach can be integrated into any existing stochastic optimization algorithms such as GA (see [Ul Abedin 2019](#)), simulated annealing and particle swarm optimization.

Objectives

In this study, two objective functions are selected. For passengers, total travel costs are considered, including origin waiting time, in-vehicle time, transfer waiting time, and transfer penalties. For operators, only the operational costs are considered; these include

Table 1 Classification of studies related to TNDFSP

on-vehicle crew cost, vehicle operating cost, infrastructure maintenance cost, and overhead costs. These operational cost components are adopted from the [Australian Transport Council \(2006\)](#).

$$\min Z_1 = OwT + InVehT + TwT + tp.NoT \quad (1)$$

$$\min Z_2 = VehCrew + VehOpt + InfOptMain + Ovrh \quad (2)$$

Where

<i>OwT</i>	Origin waiting time
<i>InVehT</i>	In-vehicle travel time
<i>TwT</i>	Transfer waiting time
<i>tp</i>	Transfer penalty
<i>NoT</i>	Number of transfers
<i>VehCrew</i>	Hourly on-vehicle crew cost
<i>VehOpt</i>	Direct vehicle operating cost
<i>InfOptMain</i>	Infrastructure operations and maintenance cost
<i>Ovrh</i>	Overhead cost

The first term minimizes Z_1 , which is the total travel costs for all passengers. The second term minimizes Z_2 , which is the operating cost borne by the public transport operators. The selected constraints are as follows:

- The minimum number of nodes in a route must be in the predefined range (e.g., 2).
- All nodes in the network must be served by the public transport network.
- Each route must share at least one node with another route.
- Two routes cannot have the same node sequences.
- The maximum allowed transfers per trip must be below the prespecified range (e.g., 2).

Route and Network Creation

The feasible routes are created by employing the k-shortest path algorithm ([Yen, 1971](#)). There is, however, one condition that is applied when creating these feasible routes and that is a route must not deviate more than the specified detour limit (e.g., 1.4 times)

Figure 1 Example toy network, demand matrix, and k-shortest path-based feasible routes. (A) Network with stops and link lengths, (B) Demand matrix, (C) Vehicle selection, and (D) Feasible routes.

Figure 2 Public transport network created by route overlap concept.

from the shortest path. Let's consider a toy network depicted in Fig. 1A for calculating the feasible paths between selected node pairs. A total of eight feasible routes are created (Fig. 1D) among the selected node pairs.

Once all the feasible routes are created, the next step is to select a subset of routes to create a public transport network. This is done by using a route overlap ratio (ROR) concept. A ROR is the common route arcs that a potential route shares with the rest of the routes inside the public transport network. The term $A_{pr,r}^c$ represents the common arcs of the potential route pr that are shared with route r . The term $ROR_{A_{pr}}^{A_{pr,r}^c}$ is the ratio of the common arcs to the total arcs of the potential route pr . The pr is checked against all the routes R in the network for ROR. The pr will only be accepted if its value is less than the β for all public transport routes.

$$N_{pr,r}^c = N_{pr} \cap N_r; \quad \forall r \in R, \forall pr \in PR \quad (3)$$

$$ROR_{A_{pr}}^{A_{pr,r}^c} = \frac{A_{pr,r}^c}{A_{pr}}; \quad ROR \leq \beta, \forall r \in R, \forall pr \in PR \quad (4)$$

To understand the concept, let's consider the feasible routes from Fig. 1D. There are eight feasible routes and the β value is set to 0.35. The first route is inserted in the network, because it is the first route to be inserted, no comparison is required. For the second route it will become a potential route, and it will be checked against the first route. There is only one common arc between route1 and route2, with the ROR value of 0.33. This is acceptable; therefore, this route is inserted into the network.

$$N_{pr,r1}^c = ((n_0, n_2)) \quad (5)$$

$$ROR_{A_{pr}}^{A_{pr,r1}^c} = 0.33 \quad (6)$$

The third route becomes the potential route. However, this time there are two routes in the network to compare to. The ROR for first two routes are 0.33 and 0.66, among which the overlap with route2 is higher than the threshold value of β . Therefore, route3 will be discarded.

$$N_{pr,r1}^c = ((n_0, n_2)), \quad N_{pr,r2}^c = ((n_0, n_2), (n_2, n_4)) \quad (7)$$

$$ROR_{A_{pr}}^{A_{pr,r1}^c} = 0.33, \quad ROR_{A_{pr}}^{A_{pr,r2}^c} = 0.66 \quad (8)$$

In similar fashion, other routes are evaluated and the final network includes route1, route2 and route5, and these routes are depicted in Fig. 2.

Demand Assignment

The demand assignment is an important component in the design of a public transport network. It helps in estimating: (1) the passenger behavior for route choice in the network, (2) the accumulated demand loads on different routes within the network, and (3) appropriate headways to offer adequate supply for required demand. According to de Dios Ortuzar and Willumsen (2011), there are two basic assignment methods: (1) headway based and (2) schedule based. A headway-based assignment is ideal for strategic

Table 2 Stakeholders perspectives with related performance indicators

Perspectives of stakeholders	Performance indicators								
	Route overlap index	Empty seat hours	Avg num of transfers	Required seating capacity	Unsatisfied demand percentage	Total network length	Travel time	Operating cost	Transport network directness
Passenger	■		■		■		■		■
Operator	■	■		■		■		■	■
Authority	■	■	■	■	■	■	■	■	■

**Figure 3** Route choice for headway and schedule-based assignment *Source: Spiess and Florian (1989).*

planning, as it involves relatively lower computation costs and requires less information for assignment. A timetable-based assignment is ideal when detailed analysis about the service being offered is required, such as actual arrival, departure time, and individual vehicle loads.

Based on the selected assignment method, the next step is to select the most suitable route choice model, in which passenger behavior is modeled based on the path or set of paths the passenger will choose to complete the trip. For the headway-based approach, the concept of optimal strategy is used, meaning that a passenger does not select an exact path, but rather considers a set of attractive paths. **Fig. 3A** shows a small example composed of four routes and four stops (A, X, Y, and B) for the given origin--destination (OD) pair. A typical strategy for a passenger would be that the passenger arrives at stop A from origin O, he/she will consider whichever vehicle comes first from either Route1 or Route2. If a vehicle from Route1 comes first, he/she will exit at stop B to destination D. If a Route2 vehicle comes first, he/she will transfer at stop Y to either Route3 or Route4 and then exit at B to the destination D.

In the schedule-based approach, the passenger has prior spatio-temporal information about the individual service runs. Based on the passenger's selected departure time, different access stops and service runs are available to him/her. In **Fig. 3B**, two different runs for two routes are available from stop A from origin O to the destination D. In this case, based on the access time t_1 to stop A, a passenger can consider taking either Route1 – Run4 or Route2 – Run6. In Route1 – Run4, he/she will exit at B through t_2 to reach destination D. If Route2 – Run6 is selected. Then, based on arrival time of Run6 at stop X and departure time of Route3 – Run2, the passenger can consider Route3 – Run2 at stop X or Y and exit at stop B to reach destination D through t_2 .

Holistic Network Evaluation

The evaluation of public transport networks usually provides a set of metrics for judging their quality from different perspectives. As previously mentioned, there are three main stakeholders in the system: passengers, operators, and authorities. The proposed transport network evaluation component considers all these perspectives and tries to perform quantitative and qualitative analysis of a public transport network. A total of nine indicators representative of all these three stakeholders are used for the evaluation. These three viewpoints with their associated indicators are listed in **Table 2**.

Figure 4 Three different public transport concepts. (A) Transfer-based network. (B) Trunk-&-feeder network. (C) Direct network.

- The route overlap index is adopted from [Vuchic \(2005\)](#), which measures the redundancy in the public transport network.
- Empty-seat hours is adopted from [Ceder \(2016\)](#) and measures the unutilized available seat capacity in the public transport network over a given time period.
- The average number of transfers measures, on average, the number of transfers required to complete the trip.
- The required seating capacity measures the total number of seats required to satisfy the demand for a given time period.
- The unsatisfied demand percentage measures the percentage of demand that is unable to complete the trips.
- The total network length measures the combined length of all the routes in the public transport network.
- The travel time measures the total travel time that all the passengers spend in the public transport network.
- The operating cost measures the cost borne by the operator for offering public transport services.
- The transport network directness measures the directness of the public transport network for all routes compared to the shortest paths.

Example

By using the route overlap concept, different types of public transport networks can be designed. Let's consider the network and the demand matrix depicted in [Fig. 1](#). Three different types of networks (see [Fig. 4](#)) can be created: (1) a transfer-based network, (2) a trunk-&-feeder network, (3) a direct network. A headway-based assignment along with optimal strategy for route choice is used for this example. Moreover, the headways and the number of vehicles required to provide the adequate supply are listed in [Fig. 1C](#).

All three networks have different attributes and functions. The transfer-based network require transfers for most OD pairs to complete the trip. The maximum allowed ROR is set to 10%. The trunk-&-feeder network utilizes the concept of a trunk route with feeder routes, with the maximum allowed ROR set to 25%. The direct network offers direct trips to most OD pairs, with maximum allowed ROR value of 100%. Let's evaluate these three networks based on the selected performance measures mentioned in the previous subsection. The travel-time components of these three networks is depicted in [Fig. 5A](#). One can see that the all three networks depict comparable travel times, with the direct network offering the least travel time. However, if both objectives are considered (see [Fig. 5B](#)), direct network cost almost 50% more than trunk feeder and transfer-based network.

The results from [Fig. 5](#) show that these networks offer trade-offs among selected objectives. Therefore, in order to see a more holistic picture, results from other related performance measures should also be analyzed. The results from selected performance measures are listed in [Fig. 6](#).

- The route overlap index (see [Fig. 6A](#)) shows that the transfer-based network and trunk-&-feeder network offer the least overlap between the routes, whereas the direct network offers three times the overlap of the transfer-based network.
- The empty-seat hours show that the maximum utilization of the offered capacity is attained in the trunk-&-feeder network and the transfer-based network, whereas in the direct network, we have the largest the unutilized capacity.
- The average number of transfers shows that the direct network offers the least number of transfers compared to other two networks (see [Fig. 6C](#)).
- The required seating capacity shows (see [Fig. 6D](#)) that the trunk-&-feeder network and transfer-based networks need the lowest number of seats for required service. This is due to better utilization of routes.
- The unsatisfied demand percentage for all three networks shows that these networks fully satisfy the demand with no OD pair requiring more than two transfers (see [Fig. 6E](#)).
- The total network length suggests that the transfer-based and the trunk-&-feeder networks require one-third of the length of the direct network (see [Fig. 6F](#)).

Figure 5 Travel time components and objective values for different network concepts. (A) Travel time components for different public transport network concepts. (B) Objective Z_1 and Z_2 comparison.

- The operating cost shows that the costs of transfer-based and trunk-&-feeder networks are two-third of the direct network (see Fig. 6G).
- The transport network directness shows that all three networks have similar directness values (see Fig. 6H).
- In terms of the required fleet size (Fig. 6I), the transfer-based and trunk-&-feeder networks requires lesser, but higher-capacity models compared to the direct network, which requires a much higher number of low-capacity vehicles.

One can see from the results of these performance measures that the transfer-based and trunk-&-feeder networks offer slightly higher travel times compared to a direct network. However, they are operationally viable, cheaper to operate, simple and easier to manage.

Summary and Conclusion

Public transport networks around the world are regularly tweaked or realigned slightly to attain route- and/or corridor-level enhancements. However, until very recently, it was not common to do major redesigns/restructuring of a whole public transport network. The availability of data and the demand for efficient, effective, operationally viable, and, most importantly, reliable public transport service convinced many public transport authorities to restructure their whole network. This helps in improving network realignment with changes in demand patterns, simplification of the network with high-frequency services, enhancing priority measures, and service reliability.

A recent study conducted by the National Academies of Sciences, Engineering, and Medicine (2019) about bus-network redesign in North America involved a survey about bus-network redesigns among 36 public transport authorities. The survey revealed that the main objectives for bus-network redesigns are: (1) to restructure the network, (2) to increase efficiency and effectiveness, (3) to

Figure 6 Evaluation of three different public transport network concepts. (A) Route overlap index. (B) Empty-seat hours. (C) Average number of transfers. (D) Required seating capacity. (E) Unsatisfied demand percentage. (F) Total network length in km. (G) Operating cost in \$/hour. (H) Transport network directness. (I) Required fleet size.

introduce the concept of a high-frequency network, (4) to simplify the existing network for ease of use, (5) to improve the reliability of the service, and (6) to increase the ridership of the system.

Among these 36 public transport authorities, one-third of them have completed a bus-network redesign, while more than half of them are either engaged in or currently involved in different phases of bus-network redesign implementation. More than 85% of these agencies have either performed or intend to perform a full redesign of the system. Roughly more than 50% of these agencies

redesign the network from scratch compared to 46%, which redesign the network based on the existing network. In terms of timeframes, for 80% of these authorities, it took at most 2 years for bus-network redesign from planning to implementation.

After the implementation, 70% of these authorities believe that the operating cost increases up to 10%. The evaluation criteria used by these agencies involves area coverage and impact on travel time, cost, transfers, accessibility, and on-time performance. Overall, such a redesign exercise has a positive impact, including increased ridership, improved operational management, and an improved level of service.

The National Academies survey revealed two things: first, that the redesign of public transport networks is inevitable and must therefore be carried out to improve the offered service quality, its efficiency, and reliability; and second, that its holistic evaluation must include perspectives from all three major stakeholders—that is, passengers, authorities, and operators.

At present, most of the work done in redesigning networks is carried out using expert opinion along with geographic information system tools. Network redesign can benefit greatly from adopting an algorithmic approach to assist the transport authorities in charge. Such an approach aids in designing different network configurations together with their evaluations, making the whole process of redesigning transparent, effective, and less time consuming.

Technological innovations such as electric vehicles and autonomous driving, along with the availability of static and dynamic data sources coupled with high computation power, provide new insights into mobility, thus generating new ideas such as mobility as a service, on-demand micro-transit, dynamic routing, and scheduling. These new ideas should be incorporated during the redesign process and/or enhancement of existing public transport networks to see how public transport can benefit with regard to service standards, efficiency, cost reduction, and reliability.

The public transport planning is an extremely complex task with route planning being one of its sub-tasks. It is extremely difficult to encompass every aspect of its planning procedures. Therefore, for a further understating of how the public transport planning process relates to future perspectives and implications of mobility automation some literature is suggested in the list of further reading.

Acknowledgment

We are grateful to TUMCREATE in Singapore to allow us for using some of their data for the analysis of this chapter.

Zain Ul Abedin is a research fellow at TUMCREATE Ltd. His main research area includes public transport network analysis, new service design, and network evaluation. He is a member of the rapid road transport group within TUMCREATE, which is responsible for designing a new public transport concept called dynamic autonomous road transit (DART), an efficient, flexible, modular, road-bound autonomous vehicle-based system. He designed the strategic network concept for DART and is involved in the identification of a suitable corridor for such service design in real networks.

Avishai (Avi) Ceder is a Professor at the Technion—Israel Institute of Technology, and Honorary Professor at the University of Auckland, see <http://ceder.net.technion.ac.il>. He is the founder and director of the Transportation Research Centre (TRC) in Auckland, the head of the Transportation Engineering and Geo-Information Department at the Technion, and the chief scientist of the Israel Ministry of Transport. He is a member of various international symposia (e. g., ISTTT, CASPT). In 2007, he released a book *Public Transit Planning and Operation*, published by Elsevier, Oxford, UK, with its second edition appearing in 2016 by CRC Press, Boca Raton, US, followed by translations into Chinese (2017) and Korean (2018).

Introduction

All transportation is about the controlled movement of a vehicle so it can travel to an intended destination. This means applying forces on that vehicle to achieve the controlled motion and that in turn means applying Newton's third law of motion. In other words, the vehicle must push against something in order to move. All terrestrial transport, such as cars and trains, push against the solid earth, at sea, propeller and paddle driven ships push against the water, and aircraft engines push against the air. The problem for Space vehicles is that for practical purposes space is empty—there is nothing to push against. The only solution to this problem is the vehicle must carry on board the mass to react against, and any vehicle that carries its own reaction mass (called propellant) is a rocket. So Space transportation is fundamentally about rockets.

To apply force, a rocket vehicle expels some of its propellant with a velocity c , called the exhaust velocity. When this happens the mass of the rocket vehicle, M , is reduced by the propellant expelled, dm . Then, by conservation of momentum, the velocity change to the vehicle dV can be found from:

$$dV = \frac{c \, dm}{M}$$

If many of these dm -sized packages of propellant are expelled, then the total velocity V can be achieved by integrating the following equation:

$$\int_0^V dV = c \int_{M_s}^{M_e} \frac{dm}{m}$$

Where M_s is the mass, then the rocket starts operating, and M_e is the mass when it finishes. Solving this integral gives:

$$V = c \ln \left(\frac{M_s}{M_e} \right)$$

This is known as the “rocket equation” and it shows the two principle drivers of astronautical engineering, the rocket engine's exhaust velocity and the fraction of the vehicle that can be propellant. For chemical rockets, the exhaust velocity varies around 3 km/s for the best solid propellant rockets where the chemicals are stored and then burnt in a tube (like a firework rocket) to 4.5 km/s for an engine using liquid hydrogen and liquid oxygen. The Space Shuttle (**Fig. 1**) had both types of engine—two solid fuel boosters that are thrown away after 2 minutes of flight, and a cluster of three main liquid engines that powered the Shuttle's Orbiter into Space.

This chapter first considers the history of rockets moving from sub-orbital to orbital flight and then outlines modern launch systems and the missions they undertake. It then discusses the impact on satellite design and then a section on the economic drivers leading to a section on the introduction of reusable vehicles. Finally, the paper considers the systems used for inter-orbit transportation.

Orbits and Sub-Orbits

Although there is no clearly defined place where the atmosphere stops and Space begins (called the Karman line), it is generally taken to be 100 km altitude. To reach it with a rocket will require a velocity of about 1.4 km/s, a feat first achieved by the German A4, a

Figure 1 The Space Shuttle at launch with three liquid propellant engines on the core and two side mounted solid propellant boosters. *Source: NASA.*

Figure 2 A V2 rocket take off. *Source: https://commons.wikimedia.org/wiki/File:The_V2_Rocket_BU11149.jpg*

prototype of the V2 missile, during its test program. This had a mass of 12.8 tons of which 8.7 tons was propellant, the alcohol/oxygen engines had an exhaust velocity a little over 2 km/s poor by today's standards (Riedel, 2005). The rocket equation predicts that this should give V2 a speed of 2.3 km/s but in practice, air resistance and counteracting gravity reduced its actual speed to 1.6 km/s. But this is enough to reach a maximum altitude of 175 km—well into Space (Fig. 2).

Gaining enough speed to get over the Karman line is a class of flight called “sub-orbital.” Any missile with a range of a few hundred kilometres can do this, but it has also been used by many scientific rockets (called sounding rockets) and is the objective of several companies who are offering tourist space flights, such as Virgin Galactic and Blue Origin. The problem with such trips is that they are brief. To quote an old adage “what goes up, must come down,” and anything on a sub-orbital trajectory will have only a few

minutes in Space before it re-enters the atmosphere, and if it does not wish to crash into the ground, it must now take out over 1 km/s velocity within the height of the atmosphere; leading to high deceleration forces of several gravities.

However, that old adage about the inevitable fall is not quite right. If an object can both reach Space, which we have seen requires over 1 km/s vertically upward, AND attain a velocity of over 7.8 km/s in the horizontal direction, then it enters the orbit and does not fall back to the ground. That means the rocket has to provide about 5 times the velocity and 25 times the energy than required for sub-orbital flight. So, it is much more difficult to achieve but if you can achieve it then you are permanently in Space. This is the basic goal of a Space transportation system—to reach orbit and then move between orbits.

The first rocket to achieve this feat was the Russian R-7 Semyorka, which launched Sputnik 1 on 4th October 1957. Like the V2, it was born out of a military program. The R-7 was developed as an intercontinental missile with a nuclear warhead and the ability to reach orbit was a serendipitous consequence of this requirement. Sixty years later this rocket, upgraded and renamed “Soyuz,” remains one of the world’s main launch systems, capable of putting around seven tons into low Earth orbit.

Modern Launchers

The Soyuz launcher (**Fig. 3**) follows the basic approach used by all launch systems in that it has stages; two or three rockets are stacked on top of each other and then fired in sequence. Once air resistance and supporting the rocket against gravity is accounted for, the velocity that should be put in the rocket equation for an Earth orbit launcher is around 9.4 km/s. Even if the propellants are hydrogen and oxygen, this means that 89% of the take-off weight of the launch vehicle needs to be propellant. With today’s technology, it is not possible to make practical rockets with meaningful payloads that can achieve this mass ratio. However, if we have two-staged rockets, they only need to reach 4.7 km/s each and then these stages only need to be 75% propellant, which can be easily achieved with rocket technology from the 1950s.

Currently, there are 30 operational launchers around the world and all are staged systems ([Stakem, 2017](#)). However, unlike the very early launch systems, which were mostly based on military missiles, today’s launchers are nearly all specialized developments to reach Space. There are several drivers creating this divergence. As technology progressed in the 1960s, the differing requirements for a

Figure 3 The Soyuz launcher which is a modernized version of the rocket that carried the world's first satellite, Sputnik 1. *Source: Arianespace.*

military missile and a launch system meant the optimum technical approach for each significantly changed. Another difference was the need for larger launch systems to meet 1960s space race ambitions, while at the same time missiles could be made smaller as warhead masses reduced.

There was another more economic factor that drove the size of launch systems up. The dominant factor that determines the cost per kilogram into orbit with expendable rockets is their size. If you double the size of the rocket, you can get a better ratio of propellant to dry mass (so more kilograms of payload) and while the costs such as development, build and operation rise as you would expect, none of them double. The end result is that the cost per kilogram drops dramatically, as launch systems get bigger. This is the economic reasoning behind “launch share” where two or more satellites are launched together. An approach that has been most successfully employed by the European launch system operator, Arianespace. Their launch systems Ariane 4 and Ariane 5 were both sized to carry two satellites at once which gave them a significant competitive advantage and they became the dominant system for launching satellites intended for geostationary orbit, managing to capture half the available market.

Geostationary orbit is a circular orbit in the Earth’s equatorial plane at a high altitude of 35,786 km. At this height, the period of the orbit exactly matches the 24-hour spin of the Earth and so the satellite appears to hover in the sky, which is why domestic TV satellite dishes can be pointed at them. The value of this location for communications was first pointed out by Arthur C Clarke in 1945, and today there are several hundred satellites typically with a mass of a ton or two. This orbit is so crowded that some satellites are separated by less than 100 km.

Another popular class of orbit are polar orbits; that is where the orbit flies over the Earth’s poles. These are valuable for observation of the Earth’s surface, as any satellite in these orbits will fly over the Earth’s entire surface. Many applications use Sun-synchronous orbits; these orbits precess to match the Sun’s passage over the year so that they always fly over a region at the same time of day, so images taken over time can more easily detect changes on the ground.

Third important orbit location are circular Earth orbits around 20,000 km. These are used by navigation satellites transmitting the signals that enable our phones and cars to know precisely where we are on the Earth’s surface.

So most of the major applications we have found for Space require special orbits and all are significantly more difficult (i.e., require more velocity from the rocket) than simply getting into any low altitude orbit a few hundred kilometers above the Earth’s surface. This is another point of divergence between launchers and military missiles; not only are the payloads typically heavier but they need to be accelerated to much higher velocities. It is this specialization trend that is exemplified by the Ariane system being optimized for a particular orbit, the one that is most attractive from a commercial perspective.

Impact of Small Satellites

An interesting development in recent times has been the impact of the miniaturization of electronics on satellites. In geostationary orbit, the size of satellites has remained roughly the same because they are driven by the large antennas and solar arrays needed to communicate with the Earth, so the technology improvements have enabled an enormous increase in the number of communications links and the amount of on-board switching between the channels. However in other orbits this technical trend has dramatically reduced the size of satellites that are needed to do a particular job.

This “small satellite” approach became a definable movement, which took off in the 1990s as a way to reduce the cost of Space activity. The use standard commercial components, not waiting for the years it takes to get Space qualified versions, was successfully pioneered by companies like Surrey Satellite Technologies. At the end of the 1990s this trend led to a specific form of small satellite—the “Cubesat” format (Cal Poly, 2014). The Cubesat (Fig. 4) was the invention of an academic team led by the California Polytechnic State University. It laid out a specification for a standard 10 cm cube weighing no more than 1.33 kg, with double sized and triple size options. Originally, Cubesats were intended as a route for academic institutions to explore Space technology at low cost, but as the potential of modern electronics housed in this standard packaging became apparent they became commonly used for commercial applications. This standard has been so successful at making Space access to small users that currently the majority of satellites launched are Cubesats of one form or another.

Originally, the economics of small satellites were based on the principle that they could share a launch with a larger payload; using any spare mass capacity that was available. This meant that the satellite was not paying anything like the true launch cost, just something to pay for the trouble of being integrated on to the rocket, and in earlier times these launches were often free. The downside was that the small satellite had to accept the same orbit and launch schedule as the primary payload, often restricting their application to technology demonstrations.

As the importance of the small satellite increased, the compromises of the shared launched approach have become increasingly problematic. So, there has been increasing attention on developing a commercially viable small satellite launch system with a payload capability that matches the satellites that want launching. Many early launch systems, such as America’s Scout and the original Delta, the French Diamant, the Japanese Lambda 4S, and the British Black Arrow, had payloads in the tens to low hundreds of kilograms—perfect for the small satellite market. But all proved unsustainable, as scale economies caused much higher cost per kilogram than large systems, and by the mid-1970s all of these had been abandoned except Delta, which had grown to launch much larger payloads of over a ton.

So the economics of satellites and their launchers pull in opposite directions, satellites want to get smaller to be more economic and launchers want to get bigger to be more cost effective. This is not a problem that has yet been completely resolved. As an example, SpaceX developed Falcon 1 which had a payload of a few hundred kilograms but this was retired after only one commercial launch,

Figure 4 PhoneSat an example of a Cubesat. *Source: NASA Ames.*

as the price moved to reflect the real costs and customer interest dried up, so the company concentrated on the much larger Falcon 9. But the allure of an economically viable service for small satellites is still strong and several ventures persist in attempts to achieve this “holy grail.”

Economics

The apparent dominance of commercial considerations in launch systems can be misleading. With the divergence of military missiles and launch systems, launch systems could be solely civilian enterprises, with the proviso that the military also want to launch satellites with similar requirements to civil satellites and so they become a significant part of the user base. So in legal terms launch systems are “dual use” in that they have both civil and military roles. As a result, while many launch systems are the result of commercial developments even these are largely dominated by their interaction with governments to the point that there is effective market failure in the launch business.

There are about a hundred launches annually, so on average each launch system conducts around three launches a year. So, most of these systems are greatly underutilized, and owe their existence to government funding for both development and operations. The governments’ investments are for strategic reasons, including a desire to be able to launch military satellites, a need to secure guaranteed access to Space for a countries’ civilian satellites, and as a demonstration of the nation’s technical prowess. However, as a consequence there is never an intention of recovering all the national investment money through the fees charged on the open market for launches. Indeed most launchers are operated with some sort of subsidy, so not even their operating cost are covered by the fees charged for commercial launches.

In this context “value for money” for the governments footing the bill means the smallest development cost, and expendable launch systems are much cheaper to develop. So almost all current launchers are still like missiles, one shot systems that are used just once and thrown away. Given that they cost almost as much as a civil airliner to manufacture, it is hardly a surprise that the cost of reaching even the easiest orbits is around \$10,000 per kg. However, high costs are not the only penalty when using expendable rockets. Because launchers cannot be flight-tested, they have a failure rate that would be unacceptably appalling in any other context. Even the best launch systems fail between one in 70 and 1 in 90 flights, and every failure is a crash and the payload is lost. Another major problem with expendable launchers is availability. As each launch vehicle as to be made especially for each payload, it has to be ordered several years in advance.

Reusable Systems

Cost, unreliability, and unavailability are the trio of constraints holding back the development of space activity and they are inherent in basing the launch infrastructure on expendable rockets. The obvious resolution of all three is to use reusable launch systems. A reusable vehicle should operate like an aircraft, it waits in a hanger, ready for launches at short notice, and because it is flown many times the cost of each flight comes down by an order of magnitude, and the vehicle is more reliable.

The reason that expendables still dominate the launch system market place is the high acquisition cost (development and build) of a reusable system which has to be recovered from the restricted market for launches, which is rather a “chicken and egg” problem as the market is restricted because of the problems with expendables. There are two ventures, SpaceX (**Fig. 5**) and Blue Origin, who are developing and operating systems with reusable first stages, with plans to evolve to fully reusable systems later. However, it is significant that both are privately funded by very high net worth individuals with a very long-term outlook and are not at the mercy of government funding corridors, or a commercial demand for rapid return on investment ([Davenport, 2018](#)).

Figure 5 Two SpaceX Falcon Heavy booster rockets return to their launch site. *Source: SpaceX.*

Figure 6 SABRE air-breathing rocket engine. *Source: Reaction Engines Limited.*

Reusable launchers cost more to develop, in part because they require additional systems like heat shielding, a means to fly back and landing gear, but also because there is a much bigger development testing program. For a two-stage vehicle, the cost is not affected by the technology employed, as the requirements are not very exacting and the technology readiness level achieved by aircraft and expendable launchers in the 1960s is more than adequate.

However, ideally what is needed is a single stage to orbit reusable launcher. As we have seen, this is on the very boarder line of possibility for expendable rockets let alone a vehicle with all the extras needed for reusability. A few ventures have seriously tried this approach but none has succeeded. However, the ideal of a reusable single stage to orbit may be possible if an air breathing engine can be used while the system is rising through the atmosphere. Air-breathing engines consume much less propellant to achieve a given thrust and could add enough performance to get a rocket from the ground to orbit.

But air breathing is not magic; the air the engine uses creates a drag as it matches the speed of the engine. This is called “momentum drag” and for practical purposes as the speed reaches somewhere between Mach 5 (5 times the speed of sound) and Mach 6 the force required to collect the air is comparable to the thrust of the engine and the system cannot accelerate further. The system is likely to be flying at over 20 km altitude when this speed is reached so in terms of reaching orbit it has done about 20% of the job, leaving the remaining 80% to be done using pure rockets. While this makes a significant difference, the weight of the air breathing machinery now needs to be added to the dry mass, and generally air-breathing engines are heavy for the thrust they produce. This means the engines used by aircraft do not work in the context of single stage to orbit vehicles and it requires a special lightweight engine which can provide the performance boost while in the atmosphere, but at the same time not cripple the mass ratio for the rocket powered phase of the flight.

The most mature example of this approach is the SABRE engine (Fig. 6) being developed by Reaction Engines in the United Kingdom (Varvill and Bond, 2003). This uses a pre-cooler to take heat from the air so that it can be compressed and fed into a high-pressure rocket combustion chamber; the heat is transferred into a helium loop that uses the energy to power the pumps and compressors. One elegant feature of this engine is that once the air-breathing limits have been reached, the engine can become a pure rocket engine, so the vehicle does not require two separate engines.

An alternative air-breathing approach is to reduce the momentum drag by not stopping the air as it travels through the engine. These are called scramjets—a contraction of supersonic combustion ramjet—because the air stays supersonic while the fuel is burned and the exhaust accelerated. They have the attraction that they should be able to travel way beyond Mach 6, but their problem is they

do not work below Mach 5 meaning another engine is needed to reach that speed. A further problem is they are heavy and large and so they need to be able to reach very high speeds (Mach 16 or more) to compensate for this performance disadvantage. There have been some experimental test vehicles to explore this engine type but they have only had limited success and currently the technology falls way short of what is required for a single stage to orbit vehicle.

Inter-Orbit Transport

Although it was over 60 years ago that mankind first acquired the ability to reach orbit, the fact that the transport system that achieved it is still a viable launch system, indeed arguably the best launch system, suggests the field has not made much progress since. Reusable systems once operational have the promise to greatly improve the way we reach orbit, and then the main area where Space transportation technology will need to advance, are the systems that operate from low Earth orbit to higher orbits, the Moon, and the planets beyond. These missions require velocities approaching what is required to reach low Earth orbit in the first place, for example, to deliver a satellite to geostationary orbit or to a lunar orbit requires around 4 km/s and to reach Mars orbit requires 6.6 km/s. At the moment around 3 km/s of this is supplied by the launch system, which puts the payload directly into a transfer orbit, bypassing low Earth orbit. In terms of energy, this is slightly more efficient but it still requires a typical satellite to provide between 1 and 2 km/s with their internal propulsion for the final orbit insertion maneuvers.

However, once in Space new forms of propulsion are possible with much higher exhaust velocities. These technologies do not use chemical energy sources and could offer a more efficient way of traveling in space, a game changer that could be as significant as the introduction of reusable launchers. But, if the chemical energy in the propellants is not providing the energy, the key problem becomes how the energy to be generated is?

The power required by a rocket engine is determined by its exhaust velocity and thrust by the simple relationship:

$$\text{Power} = \frac{1}{2} \times \text{Thrust} \times \text{Exhaust velocity}$$

Each of the Space Shuttle's main engines has a power of 5 GWatts and, when combined with the solid propellant boosters, the total power of the Shuttle on launch was around 50 GWatts, which is considerably more than the average power consumption of the United Kingdom. This is the key reason non-chemical propulsion is most suited for use in space. To take off from the Earth, the rocket needs to have more thrust than the weight of the launch system, but if we raise the exhaust velocity to get the same thrust, the power required also rises and that must come from an on-board system that delivers many power stations worth of watts. However, once in orbit a rocket no longer needs to overcome gravity and can move around with the tiniest of thrusts. So, here it is possible to have very high exhaust velocities with realistic power levels, but with miniscule thrusts.

The most mature advanced rocket engines are in a class generically known as electric propulsion. The most widely used of these engines are "ion thrusters" which ionize the propellant and then electrically or electromagnetically accelerate the ions. These engines have been successfully used on both planetary missions and geostationary satellites. An example is the QinetiQ T6 ([Fig. 7](#)), which has an exhaust velocity around 40 km/s, but a thrust of only a fifth of a Newton ([Lewis et al., 2015](#)). It needs around 4 kW of power, which is consistent with the solar electric arrays used by satellites. This engine was used in the propulsion stage of the BepiColumbo mission to the planet Mercury, and similar engines are increasingly common on geostationary satellites to perform the final orbit insertion and then keep it on its orbital station.

There are downsides to the very low thrust. The transfer trajectories they follow typically double the velocity requirements in the rocket equation, but this of course is more than compensated for by the order of magnitude improvement in the exhaust velocity. A more important downside is the increase in travel time, journeys that take hours or days with high thrust chemical rockets, take months or years with electric propulsion. While this can be tolerated for robotic satellites and probes, it is a serious problem for human spaceflight. To get travel times down to something appropriate to human mission to geostationary orbit, or the Moon or

Figure 7 A QinetiQ T6 ion engine firing. *Source: QinetiQ Plc.*

Mars will require high thrust and that means high power, GWatts, coming from generators that weigh only a few tons and, with our current knowledge of physics that means nuclear power.

In the 1970s, NASA came very close to completing the development of a nuclear fission engine called NERVA (Robbins and Finger, 1991). This had a thrust of around 30 tons and an exhaust velocity of 8.3 km/s (a power level of 1.3 GWatts) and was intended to be the primary means by which American astronauts would reach the Moon and Mars. This engine had a simple cycle; hydrogen propellant was heated by passing it over the hot nuclear core. Using existing technology in more complex cycles involving further heating of the propellant by electric arc-jets (also powered by the nuclear reactor) could raise the exhaust velocity to over 12 km/s (Bond, 1972). Beyond that, engines using nuclear fusion power, while outside our current abilities, could in theory provide high thrust with exhaust velocities up to 100,000 km/s (Sutton, 1975).

Summary and Conclusions

Currently, Space transportation is still at its most primitive stage; dominated by expendable chemical rockets giving a restricted, high cost and unreliable means to reach orbit. Despite these issues, a viable Space industry has evolved to explore and exploit the Space environment. However, with technology we have had for many decades, we can improve the Space transportation infrastructure, through reusability and advanced non-chemical rocket engines. These technologies are slowly being introduced and, when they take their full effect, the impact on the size and scope of the Space industry is likely to be considerable.

Biography

Mark Hemsell worked for 13 years as a spacecraft systems engineer at British Aerospace in Stevenage, then for 17 years at the University of Bristol lecturing in Astronautics. In 2009, he joined Reaction Engines Limited as the Future Programs Director responsible for the SKYLON airframe. In 2013, he left Reaction Engines to form Hemsell Astronautics Limited to further his interest in space systems engineering. He is a Fellow and past President of the British Interplanetary Society twice, and a former editor of the Society's Journal.

Introduction

A pipeline consists of a line of pipes that is equipped with control devices for the movement of solids and fluids. Tubes can be made of metal, concrete, clay products, and plastics. The different sections are welded together and usually placed underground. Pipelines have represented the preferred mode of transportation for fluids since the Bronze Age when they were used for water supply. Regarding the transportation of solid particles, coal and other minerals can be moved over long distances, while mail, envelopes, grain, rocks, cement, concrete, and solid wastes are conveyed over short distances. The transportation of freight through pipes brings potential advantages over currently used methods: transiting of consumer goods takes place underground, within an automated transport infrastructure that is separated from passenger traffic. Managing traffic flows in such a way would be beneficial not only in congested centers but also for decongesting traffic jams on highways (Turkowski and Szudarek, 2019).

The freight pipeline transportation was conceptualized in the 19th century for conveying mail and small packets. According to this concept, goods were charged into a capsule (unit of carriage) that was propelled by a fluid along the pipeline network. Two different technologies have been defined depending on the fluid's nature: when the propeller is a gas, the system is termed “pneumatic capsule pipeline,” conversely when it is a liquid, the system is called “hydraulic capsule pipeline.” The fluid can be blown down or extracted from the pipeline, the difference of pressure between the two ends of the cylindrical container pushes this along the tube. The system layout was completed by the loading terminal (where cargo entered the system) and the unloading terminal (where cargo left the system), as depicted in Fig. 1 near here.

When it came to moving cargo units through pipes with a diameter longer than one meter, the aforementioned propulsion technologies show lower effectiveness as well as excessive energy consumption. Hence, an optimized configuration combining linear electric motors with the advantages of evacuated tubes (minimized drag) was implemented. Such freight transport systems could be a valid alternative for, but also an addition to existing transport modes. This would also contribute to solving issues related to noise, air pollution, and global overwarming phenomena.

The chapter is structured as follows: an introductory section that describes the pipeline transportation technology and which also explains limits and advantages; a *History and development* section where milestones in pipeline evolution are summarized; a section about taxonomy which focuses on defining a cluster of parameters for pipeline transportation systems' classification; a *Future trends* section describing the upcoming innovation; a conclusive section which recapitulates the potentials in pipeline transportation.

History and Development

Pneumatic Capsule Pipelines during the Victorian Age

Pneumatic transportation was firstly theorized and developed by William Murdoch around 1799. Back then, the British engineers were the only ones investigating the potentials of pneumatic capsule pipeline in transmitting telegrams. Small envelopes were

Figure 1 Drawing from the database *Chronicling America* at the Library of Congress that represents the terminals of the pneumatic capsule pipeline.

sealed into capsules and conveyed between two places by the pressure of air and vacuum ([Fig. 2](#)), as reported in Josiah Latimer Clark's patent (1854). The first line was installed in 1853 between the offices of the Electric and International Telegraph Co. and the London Stock Exchange. The pneumatic tube negated the need to employ runners to carry messages between the two buildings, while guaranteeing speed and independence from weather conditions. Next, the Electric and International Telegraph Co. implemented similar systems in Liverpool, Birmingham, and Manchester. By 1880, there were over 30 km of tubes in London, which increased to 64 km in 1909. From the mid-1860s to the late-1890s, such systems became operational in the rest of the world: Berlin, Munich, and Hamburg in Germany; Vienna in Austria; Prague in Czech Republic; Rio de Janeiro in Brazil; Dublin in Ireland; Rome, Naples, and Milan in Italy; Paris and Marseille in France; New York City, Boston, Philadelphia, St. Louis, and Chicago in the United States; Melbourne in Australia; Tokyo, Osaka, Nagoya, and Kobe in Japan ([Bush, 2017](#)). From 1859, wheeled capsules were also tested by the London Pneumatic Dispatch for the movement of heavier cargos (up to three tons). A prototype of the Pneumatic Passenger Railway was realized in New York for the movement of people, as shown in [Fig. 3](#). However, the evolution of the telecommunication methods into the modern ones caused the pneumatic tube to lose its importance. In 1874, the London Post office considered it was no longer convenient using the system, and it was closed.

The Cold War of Pneumatic Capsule Pipelines

In the 1960s, renewed concern in large-diameter pneumatic tubes started as a consequence of the growth in interest in high-speed ground transportation. The invention of the "jet pump injector" (or booster pump) for pneumatic capsule pipelines permitted moving larger volumes ([Carstens, 1970](#); [Howgego and Roe, 1998](#)). Two prototypes were realized in Stockbridge (Georgia, 1971) and Houston (USA, 1973) for transporting heavy cargo over relatively long distances ([John A Volpe National Transportation Systems Centre, 1994](#); [Vance and Mills, 1994](#)). Both the systems were named "Tubexpress" and they differ for the diameter length: the first

Figure 2 Miss Helen Ringwald works with the pneumatic tubes in Washington, D.C. in 1943.

Figure 3 The Pneumatic Passenger Railway, as Erected at the American Institute, Fourteenth Street, New York, 1867.

prototype's diameter was equal to 0.91 m, and it doubled the second's. Following this, wheeled capsules were put into operation also in the United Kingdom and USSR. A 550 m long ring was installed in Cranfield (UK) in 1976, and tests were conducted there until 1979 (Baker and Hawrych, 1982; Fidler, 1973; Simper and Baker, 1975). The experimental facility permitted collecting performance data while optimizing the design of containers and evaluating the suitability of different materials for making pipes. Concerning Russian projects, several "Transprogress" systems were built and became operational between 1971 and 1983 (Jvarsheishvili, 1981). The first was designed by SKB Transnefteavtomatika for the movement of crushed rock at Tbilisi (Georgia, 1971) along a 2.1 km long pipeline. Cargo was transported into a train formed of up to six capsules, having a maximum load capacity of 15 ton. Such a train was capable of achieving a peak speed of 50 km h^{-1} when unloaded. A similar pneumatic pipeline having a smaller diameter (0.18 m) was installed within a manufactory plant in Moscow (Jvarsheishvili, 1981). This freight transport system called "Start" was used for moving unspecified products from the working zones to the warehouses. Soviets planned to build 20 pneumatic tubes across the former USSR, and most of these were realized and used for the movement of gravel, sand, minerals, and waste. In 1980, the "LILO-2," an 18 km long mineral transport system with a diameter larger than one meter (1.22 m) was realized in Georgia, and its length was more than doubled within the following four years (until 49 km) (Alexandrov, 1978). The system, that is still the most extensive on the planet, used to move around 2 million tons per year. Also, a pneumatic tube for waste disposal became operational in the former Leningrad in 1983, but the system was dismissed before the 1990s (Bahke, 1982; Simper and Baker, 1975).

From the Occident to the Orient

Between 1975 and 1985, the major developers of pipeline transportation (USA, USSR, and the UK) attempted to find markets for their technologies (Butler et al., 1989; Institute Research Office, 1979). Although the Soviets were the most successful, the implementation of the system within the USSR was suddenly interrupted after 1985. No commercial application was found for the British technology, while the Tubexpress unsuccessfully tried to promote the construction of a pneumatic tube for the transportation of grains in Montana. After this phase, both the Soviet and American technologies were sold to Japan that had started investigating pneumatic capsule pipelines back in the 1960s (Yanaida, 1982). On the one hand, the Transprogress concept was applied to a system for the movement of limestone between the mine and the cement plant of Sumitomo Cement Company, in Tochigi Prefecture. This 1-m diameter pipeline was realized on a disused railway line in the early-1980s. Capsules were arranged into trains formed of three elements, and each capsule was loaded with up to 1.6 ton. On the other hand, Nippon Steel Corporation and Daifuku further enhanced Tubexpress technology (Yanaida, 1982). Four pneumatic tubes with different diameters (ranging from 0.2 m to 0.9 m) were constructed for testing the suitability of the system for conveying automobile parts, reliability, and durability of materials, and also operational with heavier cargos. Following this, Airapid technology was implemented. Twin tubes having a 0.61 m diameter were installed for transporting burnt lime over a distance of 1.5 km between the different areas of the steelworks (Nippon Steel Corporation, n.d.). While Sumimoto's technology was mainly exploited in temporary applications (construction of tunnels), the Airapid was exclusively used in permanent installations.

Hydraulic Capsule Pipelines in the 20th Century

In contrast to the long history of pneumatic systems, the hydraulic concept is still in its infant stage. Such technology was implemented and used by the British military for transporting war materials during World War II. Between 1958 and 1975, engineers from Canada and United States worked on the further enhancement of this method, resulting in a new type of hydraulic tube for moving compressed coal logs. This system did not require capsules; the coal was submerged in the water and propelled by the flow.

Magnetic Levitation Transport Systems

Another milestone in the history of pipeline transportation is represented by the utilization of linear electric motors for the propulsion of capsules. Such prime mover technology, also known as magnetic levitation (maglev), was originally exploited on the railway and applied in place of traditional tracks ([Fig. 4](#)). Therefore, from now on, the evolution of pipeline systems cannot be investigated without taking into account some advances in railway transportation. Progresses concerning track-based methods, which also contributed to the enhancement of pipelines will be reported in brief in this chapter. Nonpneumatic propulsion technology was subject to a US patent granted to William Vandersteel in 1984 ([Vance and Mills, 1994](#)). Such a concept was implemented on the "SUBTRANS" project, a capsule pipeline developed in the United States in 1992 and exploiting linear induction motors. The system was intended to operate at a constant speed of 100 km h^{-1} and capsules were capable of accepting pallets. In 1994, researchers at Kawasaki and NKK tested a similar prototype where capsules were pushed along a 45 m long tube by linear synchronic motors. Following this, Japanese engineers undertook test runs on "Shinkansen" trains (1997). Shinkansen trains consist of maglev vehicles, running at speed of over 500 km h^{-1} . Also, a demonstration project from Magplane Technology Co. using the same propulsion became operational in a phosphate mining company (IMC-Agrico Company) in Lakeland, Florida (2001) ([Montgomery et al., 2000](#)). Cargos were moved at a peak speed of 65 km h^{-1} through a 200 m long pipelines. At the beginning of the 21st century, an automated transport system for people called MicroRail was realized in the Texas region. According to this concept, a maglev train is supposed to run on a guideway above the ground. During 2013, Mole Solutions company realized a pipeline demonstrator near Cambridge. Two capsules, that were propelled by linear induction motors, were put into operation to convey bulk materials along a track length of 105 m. Such technology was also exploited in the CargoCap plant which was conceptualized in Germany in the late-1990s. A test track prototype was built in Bochum and it is still operating. When fully developed, this system would allow transporting consumer goods along an underground network, at a peak speed of 40 km h^{-1} .

Low-pressure Pipelines and Hypersonic Transportation

The modern age of pipeline transportation began in 1991 when Gerard O'Neill submitted a patent application describing the "vactrain" hypersonic technology ([Dyson, 1993](#)). It described a vacuum-tube train, capable to exploit magnetic levitation tracks coupled with the advantages of partly evacuated tubes. O'Neill estimated such trains could reach a speed as high as 4000 km h^{-1} if

Figure 4 A maglev train is coming out of the Pudong International Airport.

Figure 5 A test running on PipeNet prototype for testing the installed linear electric motors.

the air was completely blown out from the tunnels. During 1992, the company Swissmetro was created to develop a futuristic project for Swiss national transportation based on hypersonic vehicles (Jufer et al., 2006). Maglev trains were supposed to travel in low-pressure tunnels, connecting the Swiss network to the major pathways of the German Transrapid monorail (built in 1991). However, the project has never been realized and the company went into liquidation in 2009 because of the lack of economic support. During the same decade, the PipeNet system was implemented in Italy (Cotana et al., 2008). Research activities coordinated by professor Franco Cotana (University of Perugia) resulted in a patent that was granted in 2005. This innovative concept firstly proposed applying the vactrain technology to capsule pipelines for the movement of commodities between two hubs (Fig. 5). The fluid dynamics of a running capsule was analyzed in a 100 m long tube in Terni (Fig. 6), highlighting that such containers can theoretically achieve a peak speed of 1500 km h^{-1} . In the United States, the ET3 Global Alliance, founded by Daryl Oster, focused on the global implementation of evacuated tube transport technologies. The main findings were used for filling a US patent that was granted in 2009. The ET3 experience has significantly influenced the Hyperloop concept presented by Elon Musk in 2013. Following this, several companies such as Virgin Hyperloop One (Fig. 7), Hyperloop Transportation Technologies, and TransPod have been founded to develop such maglev system for either people or freight transportation through evacuated tubes (Janzen, 2017). Test runs have been successfully undertaken, and full-scale systems are expected to be realized soon in Texas, Colorado, Florida, Chicago, Dubai, and the United Kingdom.

Taxonomy of Pipeline Transport

In this section, a list of criteria for classifying pipeline transport systems is presented. Firstly, water and sewer lines, oil pipelines, slurry tubes, pipe networks for gases, and other fluids as liquid fertilizers, and also freight transport lines (either for light-weight or heavy cargos) can be distinguished. Furthermore, plants for people transportation have been added to these as a new category, during the 21st century.

Secondly, pipelines are classified basing on the way commodities are moved along their network. Consumer goods can be conveyed either into capsules or submerged in the fluid. Regarding capsules, these can be eventually arranged into a train.

Thirdly, the nature of the fluids filling the tubes represents a parameter for determining different clusters. The presence of fluid generally characterizes pipeline inner volume, although the movement of freights can also happen through the evacuated environment (vacuum tube). Such fluid can be the transported one (i.e., oil, slurry, natural gas) or the one pushing cargos (air or water).

Fourthly, the exploited prime mover represents another criterion for the classification. Pneumatic pumps or hydraulic pumps can be exploited for blowing in or extracting the fluid from pipes, generating thus the difference of pressure between the two capsule's ends, which is needed for the propulsion. If no pump is installed, linear electric motors are used for the movement of cargos.

Finally, pipeline transportation systems can be classified depending on the speed as well as on the covered distance. The speed categories range from low-velocity to hyper-velocity, while the ones based on the distance vary from building-scale to urban-scale, although some potential applications of the existing prototypes could even cover a whole region.

For example, two pipeline transport technologies from different ages are here defined in accordance with the criteria described in the lines above. Therefore, the system used for moving mail and telegrams between the offices of the Electric and International

Figure 6 Professor Franco Cotana and the 100 m long prototype of PipeNet system built in Terni.

Telegraph Co. and the London Stock Exchange (1853) was a “low-velocity pneumatic capsule pipeline for light-weight freight transportation at district scale,” while the PipeNet technology (2005) consists of a “hypersonic maglev capsule evacuated pipeline for heavy freight transportation at regional scale.”

Future Trends

The review of pipeline transport systems presented in the present chapter highlighted that the technology required for moving capsules and trains at hypersonic speed has been already developed, and its reliability demonstrated. During the last decades, different small-scale prototypes were realized to gain knowledge about the effectiveness of linear electric motors coupled to evacuated tubes. Therefore, the upcoming step would imply the construction of the first pilot project capable of reaching the hypothesized peak speed (higher than 1000 km h^{-1}) within a partly evacuated environment, and research groups working on such technology are rapidly approaching this goal. Switzerland is planning to construct a comprehensive system named “Cargo Sous Terrain,” that would be fully automated and designed for transporting freights and people. The first phase of this system is expected to be launched by 2030. Also, numerous companies such as PipeNet, Virgin Hyperloop One, Hyperloop Transportation Technology, and TransPod have promoted fundraising campaigns in order to support the realization of their systems. The lack of adequate safety systems to reduce the risk for the transported freights or persons currently represents a barrier to the development of hypersonic vehicles. Thus, it can be reasonably assumed that consumer goods will be traveling at such speed earlier than people due to the lower level of safety needed.

Regarding the transportation of commodities through pipelines, various diameter lengths had been tested for capsules and tubes to simulate different utilizations. In the future, these values should be leveled out and standardized. A specific regulation should assign a diameter length to the pipeline depending on the characteristics of moved freight. Sizing process of capsules should also take into account the potential interconnection with the existing logistics network. Following this, the contributions from Modular Logistics Units in Shared Co-modal Networks (Modulushca) project and the work done by Alliance for Logistics Innovation through

Figure 7 Front view of Virgin Hyperloop One XP-1 test pod on display at Rockefeller Center on September 2019.

Collaboration in Europe (ALICE) European Technology Platform would be fundamental (in Europe). The former aims at enabling operations with iso-modular cargo units, providing a basis for an interconnected logistics system for 2030. The latter has as a goal the development of a comprehensive strategy for research, innovation and market deployment of logistics and supply chain management innovation in Europe.

Finally, the further enhancement of pneumatic and hydraulic tubes should be limited to small diameter systems (and light-weight cargos) since linear electric motors have been demonstrated being more efficient when it comes to larger pipes (and heavier cargos). Improvements should consist of integrating these to the hypersonic network as last-mile transport solutions, hence delivering packs to end-users. Determining a range of potential solutions capable to solve issues concerning last-mile logistics represents another aspect that is worth investigating.

Conclusions

The increase in freight transportation and the consequent congestion of the highway and rail systems have provoked a renewed interest in alternative solutions like capsule pipelines. The implementation of the linear electric motor technology has permitted to reduce the energy consumption for propelling cargos over long distances. Also, the conceptualization of vactrain vehicles has encouraged the development of hypersonic systems capable of achieving peak speeds never experienced. Using very high-speed automated-guided capsules for the movement of freights and people would lower traffic jams, the amount of pollutants released in the atmosphere, and the dependency on fossil fuels, while increasing the level of transport security. However, such plants require the construction of dedicated infrastructure and considerable funds, and also they are still considered as too futuristic by society. Lack of social acceptance along with a shortage of policy support is widely recognized as two of the main barriers to the technology application.

Despite this, private investors are getting more and more interested in funding such projects as the cases of PipeNet in Italy, Cargo Sous Terrain in Switzerland, Hyperloop in the United States, and TransPod in Canada. The next stages and challenges have been

already identified; and they consist of realizing the first pilot systems, defining the standards regulating capsules' sizing, and investigating last-mile delivery systems. Within this framework, the contribution of governments with respect to decision making would be essential. Developing proper and integrated planning of the activities (on surface and subsurface) with adequate standards, which are established in advance, is fundamental for introducing tube transportation in congested areas.

In conclusion, the beginning of the 21st century can be reasonably considered as the turning point in the history of pipeline systems as well as transportation in general. Hypersonic technologies have been developed and previous limits concerning peak speed have been overcome, and also people are getting familiar with the "just in time" concept. Promoting an adequate regulatory framework or private initiatives is expected to represent the definitive push towards the realization of such projects.

Franco Cotana was born in Marsciano (Perugia) in 1957. He graduated in electronic engineering in 1983 at the University of Rome "La Sapienza". He was a full professor in "Industrial Applied Physics" at the University of Perugia; member of the Board of Administration of the University of Perugia from 2014 till 2019; director of CIRIAF (Interuniversity Research Centre for Pollution and Environment–Mauro Felli), based at the University of Perugia, from 2013 till 2015; founder and director of CRB (National Biomass Research Centre), a research center of the University of Perugia sponsored by the Italian Ministry of Environment, Sea, and Land Protection, from 2003 till 2013; and president and coordinator of the PhD in "Energy and Sustainable Development" at the University of Perugia. He is an author of more than 400 scientific papers and 25 patents in the fields of energetics, sustainable transports, applied acoustics, heat transfer, applied thermodynamics, and lighting design; coordinator of many national and international research projects such as the "GreenPost" and "PostalZEV" projects; national coordinator of the "FISR Vettore Idrogeno" project; member of the New York Academy of Sciences since 2010; representative of the Italian Government in Brussels for the EIBI SET PLAN Bioenergy and Renewable Fuels for Sustainable Transports; and member of the Coordination Board of the AIA-IPPC Commission at the Italian Ministry for the Environment, Sea, and Land Protection.

Mattia Manni was born in Foligno (Perugia) in 1991. He graduated in Architecture and Construction in 2015 at the University of Perugia. He worked as an urban planner on the enhancement of the suburb areas around the Perugia train station. He is doctor of philosophy in "Energy and Sustainable Development" since 2020; author of publications in the fields of energetics, sustainable development, solar analyses, smart materials, responsive building design, and low-carbon technologies. He is involved in national cluster technology projects funded by the Italian government on third-generation biofuel solutions and cooperates with the temporary working group of the SET Plan Renewable Fuels and Bioenergy IP.

Introduction and Background

The socialization of role assignments over time, with women being the care-giver and male being the breadwinner, gets reflected in access to space-time dynamics, opportunities/activities and resources. Whilst in the last couple of decades there has been a significant rise in women's participation in employed workforce, particularly in the Global North, women are still more likely than men to be the primary carer at home and responsible for various domestic tasks, and less likely to be in full-time employment. This leaves women with complex and intricate scheduling activities in both time and space (Kwan, 1999; Susilo and Dijst, 2009; Hanson, 2010). Furthermore, low mobility levels and constrained access to resources among women reduce their possibilities of solving this complex scheduling problem. This has also led to a markedly different travel behavior of women which gets expressed in the following variations:

Trip Purposes

Previous studies (e.g., Priya Uteng, 2006; Susilo and Maat, 2007) show that low mobility levels and time-space constraints, such as childcare obligation, are two important factors explaining why women tend to work closer to home and use more public transport, compared with their male counterparts. Gender differences regarding resources of time, money, skills, and technology lead to differences in the travel and transport patterns (Law, 1999), which in turn create a differentiated labor market and personalized space-time opportunities.

Since women are either unemployed, working part time, or working in close vicinity of their homes along with balancing their household responsibilities, it is noted that women make fewer job and business trips, but more shopping and escort (children and elderly) trips (e.g., Best and Lanzendorf, 2005). This has led to more varied/complex activity patterns of women (e.g., Scheiner and Holz-Rau, 2017).

Trip Chains

Following on point one, relatively higher incidences of complex trip chaining are found among women (e.g., Paleti et al. 2011; Scheiner and Holz-Rau 2017). Since women's trip chains are more complex than those of their male counterparts, they are more dependent on a comprehensive public transport network. King (1980) argued that while travel choices for men primary depend on travel time, availability and affordability are the crucial issues for women. Further, since women's travel destinations are closer to home, they are more likely to use public transport twice as often as men. However, it has been noted that the gender gap in public transport use might be reducing over time (Susilo and Maat, 2007; Hjorthol, 2008).

Daytime Distribution and Concentration of Trips

Both due to personal security concerns and as a matter of preference, women go out by night less often (e.g., Scheiner, 2013) and given their employment status, women travel less often in rush hour.

Licensing and Car Availability

Traditionally, license and car availability has been higher for men (e.g., [Hjorthol, 2008](#)) but in recent works undertaken in the Global North, it is noticed that both licensing and car availability are converging ([Scheiner 2018](#)).

Trip Distances and Trip Duration

Typically, both trip distance and trip duration have been shorter for women. This is especially the case for work trips but holds true for other purposes as well (e.g., [Hjorthol, 2008](#); [Scheiner et al., 2011](#)). It is also noted that women participate less in long distance work- or business-related travel. On average, women have shorter travel time and more non-work activities than their male counterparts (e.g., [Transport for London, 2012](#)). Recent studies, however, point toward a convergence, taking place in this arena as well. There is even a mention of “gender turnaround” in distances traveled by young people ([Tilley and Houston, 2016](#)).

Discussions expanding on one or more of these themes can be found in the following contributions of this volume:

This paper is organized as follows: after an introduction to the topic in the first, the second section expands on the thematic area of women and transport modes. Third section further builds on the topic in light of the smart cities and smart mobilities agenda. Last section presents a brief summary and concludes the chapter.

Transport Mode Choice

Traditionally, women have been car passengers, while men have been the drivers. And across the world, women use public transport and walk more often than men ([Priya Uteng 2012](#)). Given the high incidence of trip chaining, women are more multimodal (e.g., [Heinen and Chatterjee, 2015](#)). When it comes to the case of women drivers, it is noted that women typically drive smaller cars ([Choo and Mokhtarian, 2004](#)) ([Fig. 1 and 2](#)).

In the case of car driving as well, studies indicate that a convergence might be taking place in the Global North (e.g., [Hjorthol 2008](#); [Scheiner et al., 2011](#)).

To illustrate this case further, we draw on the case of Sweden where though the gender gap in terms of driving has reduced and a convergence is taking place, the gap still remains ([Susilo et al., 2018](#)). The decline in gender difference over the generations (both in total effect and in direct effect) appears most substantially in the group of partnered/married families without children (a drop from 48% in the 1930s to 18% in the 1970s). The women of the 1980s and 1990s generations still have on average 10% less car driving share than men, although that number is 30% for the 1940s generation. These trends seem to show that although more women have started driving, the gender gap in terms of driving still remains.

Regarding bicycling, previous studies have found that women's perception of danger on the road prevents them from commuting by bicycle ([METPEX, 2013](#); [Susilo and Cats, 2014](#)). [Lam \(2019\)](#) presents a synthesis highlighting that women prefer protected cycle lanes away from motorized traffic because it heightens their perception of safety ([Garrard et al., 2008](#); [Pucher et al., 2010](#); [Aldred and Woodcock, 2008](#); [Lam and Cosgrave, 2019](#)).

Lack of knowledge about bicycle maintenance and the need to do multiple trip patterns further deters women from cycling. In terms of trip purposes, [Krizek et al., \(2005\)](#) showed that women were more likely than men to cycle for shopping, making other errands and visiting friends, while they were less likely to cycle on their commute. Furthermore, they also demonstrated that women

Figure 1 Women rely more on Public Transport than men. Source: [Delatte \(2018\)](#).

Figure 2 Gender ratios—mode choice over time in Germany. Source: *Scheiner et al. (2011)*, Reproduced in *Scheiner (2018)*.

are more risk averse and show a stronger preference for safer forms of cycling infrastructure. Previous research (e.g., [Law, 1999](#); [Waygood and Susilo, 2011](#)) found that the built environment such as land use characteristics, physical layout and design of transport networks, and facilities influence the travel behavior of men and women differently. It has also been found that wherever cycling is a part of the travel culture, women bicycle longer distances).

Bicycling for women is a direct outcome of spatial planning covering issues related to safety, slow cycling and preference for dense neighborhoods. For example, a 2018 study from Stockholm, based on time-series data from 1985 to 2015, highlighted that while the gender gap in car use and bicycling “closed completely” in the inner city of Stockholm; the gap continues to exist the outer and suburban areas ([Bastian and Börjesson, 2018](#)). Similar findings have emerged from other parts of the world as well ([Abasahl et al., 2018](#); [European Parliament, 2012](#); [Sovacool et al., 2018](#))([Fig. 3](#)).

Women are also more likely than men to travel with buggies and small children for all kinds of purposes ([METPEX, 2013](#)). In major cities, this can be a stressful challenge, and some women therefore develop strategies to avoid traveling with luggage and children ([Hine and Mitchell, 2001](#)).

Figure 3 Difference in bicycling route preference between men and women in Oslo. The colors illustrate the gendered distribution of preferences for particular routes and roads for bicycling. The color *blue* represents a relatively higher share of men bicyclists while strong *red* color highlights female bicycling shares and preferences. Source: *de Jong et al. (2018)*.

Figure 4 Moving from a car-centric to people-centric approach in urban and transport planning. Source: *Svanfelt (2019)*.

Furthermore, women are thought to be more cautious in their travel behaviors than men (*Transport for London, 2009*). The customer typology suggests that women are more likely to fit into the categories of “travel shy,” “reassurance seeker,” and “cautious planner.” For all three categories, levels of confidence using the public transport network are relatively low (particularly so for those who are “travel shy”). As a result, women may choose to complete familiar journeys where possible or will seek advice and information to help them plan and complete their journeys (*Transport for London, 2009*). Among public transport users, multiple studies have argued that a safe, reliable and frequent service is extremely important for women. *Law (1999)* revealed that self-imposed precautionary measures adopted by women due to their safety concern limit their mobility significantly, especially in developing countries (*Priya Uteng, 2012; Hossain and Susilo, 2011; Tarigan et al., 2014*).

Women are more likely than men to walk the children to school (e.g., in London, 22% compared with 12% of men, respectively), and to walk to work/school/college (in London 53% of the women walk to work/school/college but only 49% of the men) (*Transport for London, 2012*).

Summing up, women drive less, walk more and use public transport more in comparison to men. But the field of transport planning has operated primarily on the principles of providing for cars, affecting negatively not only women but also the world economy at large. In Morocco, for example, 80% of women surveyed in 2010 affirmed that lack of transport provision limited their autonomy (*CoMun 2014*). In Jordan, 40% of women reported having to turn down employment opportunities solely due to access to an affordable and acceptable mode of transport. A McKinsey report from 2015 concludes that women’s employment is the driver for global economic growth and closing the gender gap could deliver \$12 to 28 trillion of additional GDP in 2025.

In light of Agenda 2030 and Sustainable Development Goals (SDGs), women as a category are the best candidates to build our planning systems around, as they both exhibit more sustainable travel behavior as compared to men and have a preference to continue doing so given supportive conditions. To put the trends in perspective, a simple calculation was done for the city of Malmö, which highlighted that if women were to adopt the current travel patterns of men, the following changes will occur (*Svanfelt, 2019*):

- the modal share by car would increase by 17 %
- CO₂ emissions from car traffic would increase by 31%
- Additional demand for driving and parking space would add up to 190 Möllvångstorget (standard town square).

Table 1 Gender split among private customers of various car-sharing providers in Europe around 2010.

<i>Car-sharing provider and/or location</i>	<i>Share of male customers</i>	<i>Share of female customers</i>	<i>Source</i>

**Figure 5** Share of female Uber service riders 2017. Source: IFC and Accenture (2018), p. 33, quoted in Lenz (2017).

In essence, both from the sustainability and gender equity perspectives, we are looking for solutions, which can cater to multi-modal trips with high priority assigned to safe walking/bicycling conditions and creation of areas which caters to multi-purpose trips and the task of trip-chaining (Fig. 4).

Smart and New Modes of Transport Provision and Women

Given this background, it becomes important to discuss the general direction which the field of urban and transport planning is taking in light of both smart solutions and new modes of mobility.

Recent Studies highlight that the uptake of the new mobility trends is higher among men in comparison to women, for example, use of BEVs in carsharing (Kawgan-Kagan, 2015), car sharing and Uber services (Lenz, 2019). To illustrate this case further, 95% users of BEVs in Sweden are men (Haustein and Jensen, 2018) while the figure for male car sharing users in Berlin remains at a staggering 84% (Kawgan-Kagan, 2015).

The main reasons cited for the adoption of electric vehicles (EVs) and carsharing include environmental awareness, affinity towards technology, and innovation as lifestyle and it is a consistent finding that women exhibit a relatively higher flexibility to adapt their mode choice in light of the cited reasons (Li et al., 2017; Rezvani et al., 2015; Shaheen et al., 2015). Studies have found and positioned gender as an important variable, but this topic has yet to be fully explored in discussions surrounding the upcoming variations of the private car. For example, Li et al. (2017) literature review of over 40 studies advertently points towards gender being a major socio-demographic factor influencing the intention to adopt an EV. Rezvani et al. (2015) found similar results while reviewing studies on the attitudes and factors influencing the acceptance of plug-in EVs (Table 1) (Fig. 5).

Gender differences can also be found in the uptake of bike sharing schemes, and provision and designing of new biking infrastructure in general. A recent study from Oslo (Priya Uteng et al., 2020) highlights that men and women demonstrate clear differences in both preference and usage of shared bikes in Oslo. Women are more concentrated on the outer fringes of the city in

Figure 6 Route mapping of shared bikes vis-à-vis share of female employment. Source: Priya Uteng et al. (2020).

terms of spatial distribution of both their residential and employment locations but the provision of docking stations for shared bikes is concentrated in the city center. Further, a high employment/residential density of women correlates strongly with high bike sharing so it seems that the mismatch between provisions of shared bikes in the peripheral areas might be leading to underutilization of the bike-sharing scheme by women in Oslo. While men primarily use shared bikes for the purpose of access and egress, women use shared bikes for multi-purpose trips (Fig. 6).

Discussing the case of London, Lam (2019) states that despite London's increased investment in cycling infrastructure and overall growth in cycling over the past two decades, the gender gap in cycling persists. The current cycling shares highlight that men make 63% of cycle journeys in the city. Lam (ibid) further compares the case of cycle superhighways versus the quiet ways to highlight the existence of multiple kinds of systemic and structural inequalities that interact in complex ways to produce uneven urban cycling experiences. She states "Specifically, implicit male bias is present in London's treatment of cycling infrastructure, representations of cycling and cyclists and 'smart' cycling innovations. Consequently, London's cycling interventions raise the profile of already-visible, privileged cyclists (predominantly white, middle-class, able-bodied men) for whom cycling is a lifestyle choice, while erasing those for whom cycling is an economic or spatial necessity" (Fig. 7).

Summary and Conclusion

Women have been the traditional users of sustainable transport modes like walking, bicycling and public transport. But given the consistent focus on cars in both urban and transport planning domains, there has been a convergence in women's usage and access to cars. But even then, differences remain which could be partially ascribed to a continued preference for using other modes than cars and the multiple roles undertaken by women, which fits well with multi-modality. Given this backdrop, women stand to gain from new, "smart" mobility services if the solutions provide for complex activity scheduling, trip chaining and varied mode usage within an affordable time and pricing range. Services that may contribute to this are, for instance, networked public and semi-private systems, such as conventional public transport linked with last-mile bike sharing, or stand-alone sharing systems, such as car sharing, bike sharing and ridesharing (Scheiner, 2018).

Introduction

Transport has long been a data-driven discipline. The requirements for transport to operate efficiently in time and space in order to fulfil its economic and societal purposes have propelled the collection of ever-growing quantities of data, and often its regulation and standardization. The standardization of time zones to regulate rail timetables is a well-known example. The transport industry also historically stores large amounts of data, from the geographical coordinates of every bus stop in a network to the outputs of large traffic counts and surveys. However, the size of a database or dataset is not the defining characteristic of what has come to be known as “big data.” Rather, this entry defines big data as:

Data that are generated automatically and collected digitally, rather than collected manually and then compiled in digital form. Data that can be described and assessed using a number of terms beginning with “V”: Volume, Velocity, Variety, Veracity, and Value.

In recent years, more transport-related data meet this “big data” definition, from electronic ticketing transactions to Automatic Number Plate Recognition (ANPR) cameras. The purposes of such data are usually operational, but data can also provide insights for transport planning and strategy. Meanwhile, the Information and Communication Technology (ICT) sector also generates big data that can be applied to the study of mobility, from the Call Detail Records (CDRs) that mobile phone companies catalogue in order to bill their customers to geo-tagged social media posts.

This paper is structured as follows: Section VThe V's of Big Data describes the defining characteristics of big data; Section Transport Big Data reviews the many sources of big data from the transport sector, including public transport, private transport, the freight industry, and newly emerging modes, and business models; Section Big Data from ICT Sources explores big data from ICT sources, such as mobile phones or applications on mobile and fixed internet services; and Section Summary and Conclusion: Implications for Uncertainties concludes this entry.

The V's of Big Data

The first “V,” Volume is the most obvious characteristic of big data. Big datasets are so large that they can be uncomfortable to conceive of and require extensive computing memory to manage. In the past, such volumes of data would have been difficult and expensive to collect and store, and retention of data over time was limited. The exponentially growing capacity of computers to file information on ever smaller drives, and the introduction of cloud computing make it possible to store big data, often through automated processes. Big data can then be retained until assessed and analyzed, which large increases in computing power and reductions in the cost of this power make possible. This inexpensive capacity is necessary not only to handle the volume of data, but also the second “V” characteristic, its Velocity. Big data are being generated ever faster through automated means, with unimaginable quantities added each second. Translating the data into use-able information in real time is a growing challenge, involving complex analytical methodologies.

The third “V” is Variety. Big data are not only numbers. Big data include sound, images, text, sensor readings of weight, speed, temperature, or environmental parameters such as pollution, or detections of an object or event. Big data can be qualitative or quantitative, official or crowd-sourced, and are generated to fulfil a wide array of functions prior to any use for research or other secondary purposes. The challenges such variety presents for analysis raise the specter of the fourth “V,” Veracity. Veracity refers to how transparent different datasets are in their source, independence, and biases, and how accurately any inconsistencies can be overcome when the data are applied or analyzed. Extracting useful, trustworthy information can be challenging when working with big data.

Which leads to the fifth and final “V,” Value, which is not always included, but raises a number of questions: Can big data be transformed into not only information, but also intelligence? Are particular big data sources worth keeping, processing, and analyzing, in financial and in ethical terms? Will the use of big data lead to more sustainable outcomes, for the economy, environment, and society? Can big data improve the practice of transport planning and operation, and the infrastructure and accessibility delivered? The rest of this entry will consider the types and uses of big data in the field of transport and aim to provide some brief, qualified answers to the above questions.

Transport Big Data

Transport big data are often generated and/or owned by transport organizations, which employ the data in order to fulfil their statutory, regulatory, or commercial functions, including delivering the basic business of mobility and logistics services and infrastructure. The organizations involved include public transport operators, haulage companies, those delivering public sector contracts on the highway network, vehicle manufacturers, and technology entrepreneurs aiming to capture a proportion of the transport market.

Public Transport

The growth of big data in the public transport sector is one of the most noticeable, as it has a public-facing aspect. While train, bus, and tram operators still publish timetables and register bus stops or map stations and other assets, many also collect data on the precise location of their services at regular intervals or at a continuous velocity. These real time information systems use Global Positioning Systems (GPS) fixed to the vehicles and to sensors at stops and stations, and often feed into screens and applications to provide passengers with more accurate information for journey planning, travel alerts, and wayfinding. The veracity of this information is high, as such systems are often designed for communicating with passengers, and research suggests that the provision of reliable dynamic information, particularly during disruptions, improves passengers’ perceptions of service quality (Pender et al., 2014). Some public transport networks have additional technology to monitor vehicle or carriage occupancy, ambient comfort, and driver behavior. As well as providing information to the customers, the variety and volume of data such systems create can be used to improve end-to-end journey times of services, smooth out headways, reduce bunching, track any disruptions or diversions, train drivers in fuel efficiency, and inform performance monitoring of delays and punctuality. Closed Circuit Television (CCTV) is also commonly used on public transport to increase security, and although such systems are often still monitored manually, new data science methodologies can be applied to image-based big data.

Electronic ticketing systems are also a major source of big data in public transport. These transactions are captured and retained for commercial purposes. However, such data have the potential to inform analyses of public transport demand across a network by time of day, season, and particular events. The data usually can be analyzed by location of boarding. Sometimes the location of alighting is also recorded or can be deduced from fare structures and timestamps. Electronic ticketing data also offer insights into the travel patterns of different passenger groups depending upon the variety of ticketing options—commuters using season tickets, youth or senior concessions, the use of a local smartcard versus an internationally recognized bankcard or mobile payment. These data inform the accounts of a public transport operating company, but can also provide intelligence on the integration of public transport networks with different land uses, which can improve the efficiency and commercial success of services through adjusting stops, frequency, and vehicle capacity. Such adjustments could be targeted to increase social equity and inclusivity, market new services, or respond more effectively to planned or unplanned events.

Private Transport

Highways authorities have a responsibility to manage their road networks and infrastructure, and thus have automated and digitized data collection both to enforce any restrictions, such as on speed or parking, and also to levy charges, such as in low emission or congestion zones. These data come in not only large volumes, but also a wide variety of forms. ANPR cameras identify individual vehicles and their movements and are often placed at junctions and key points on the network, whether as a cordon or at nodes along particular links. Other nodal data are produced by environmental sensors that automate the illumination of streetlights, monitor air pollution, or inform winter gritting rotas. As in public transport settings, CCTV may be installed for security purposes, but captures images of all road users, and thus has the potential to measure categories of transport demand at a particular location using visual recognition and machine learning methods. In urban settings, CCTV and other types of sensors identify both individuals and vehicles. Bluetooth sensors on transport infrastructure are device-based, and generate big data including timestamps and

geolocations on almost every enabled vehicle or individual device that passes. Although this does create sampling biases toward newer vehicles and younger segments of the population who hold the relevant devices and keep such connections active, such sensors can capture data that are limited in more traditional cross-sectional surveys. For example, one scheme introduced Bluetooth sensors to record travel times along particular routes, but the data were also used in research to identify temporal variability of travelers along those routes (Crawford et al., 2018).

Many of these road network technologies have become part of what is known as the Internet of Things (IoT) where cameras and sensors monitor conditions and send data back to a central control system at high velocity, often in real time. Private cars have also become part of the IoT, using vehicle telematics that communicate online to enable the operation and regular updating of features such as satellite navigation. Complex on-board computers record not just mileage, but operational aspects like speed, fuel efficiency, engine, and gear optimization, as well as offering assistance in vehicle maneuvers, using sensors and cameras for obstacle detection, lane changes, and parking. They also provide additional security and remote access to a vehicle. Many of these electronic features on private vehicles are not currently linked to the IoT nor do they necessarily save the data they generate about driving behavior over time, but the option for them to do so is available. For example, insurance schemes for younger drivers offer discounts to those drivers (or their parents) who are willing to have data on their driving behavior monitored remotely as a means to reduce accident rates and improve road safety among this vulnerable demographic.

Freight

Remote monitoring of driver activities is of particular importance to the freight industry. Freight vehicles are usually equipped with GPS and other intelligent transport systems (ITS) or vehicle telematics that track the movements and journey times of the vehicle. The freight industry also has automated means of collecting data on where inventory is loaded and unloaded, vehicle speeds, routing, weight, and driver behavior, including fuel consumption and length of time between rests. This volume, velocity, and variety of data are essential in increasing the efficiency of an industry that is dependent upon just-in-time deliveries and small margins. Thus, for operational and commercial reasons, goods vehicles are often at the forefront of Vehicle-to-Vehicle (V2V) and Vehicle-to-Infrastructure (V2I) technology, creating connected networks that enable more precise fleet management, improved driver and road safety, and the development of platooning, remote and automated control of vehicles.

Indeed, due to its innovative nature and the investment required, V2I systems tend to be installed on strategic road networks serving freight and long distance traffic before being implemented on local roads. On these networks, traffic count loops may be accompanied by sensors able to classify vehicles by weight, length and other characteristics, which are important to those responsible for managing the road network, for example, to enforce weight restrictions. Such systems have also informed early uses of big data in network management, providing infrastructure authorities with intermediate data on loads/flows on their network between fixed monitoring points. Some data are even used to determine the accessibility of major destinations or journey times to important junctions, which is then broadcast through the highway network's real time information system, that is, electronic, variable message signing (VMS). However, with the spread of vehicle telematics in not just the logistics, but also the private mobility sector, this information has begun to be relayed directly into vehicles' GPS and the satellite navigation displays.

New Modes and Systems of Mobility

Although there are some biases in the analytical methodologies and resources employed to sort through the volume, velocity and variety of big data and derive value, the sources of data described above are rarely of questionable veracity. The IoT that are built into transport networks and services are usually installed by operators or responsible parties and validated by official sources to inform network performance or service demand. Their proliferation can be seen as part of the current pace of change in the transport sector as it accommodates the increasing automation of mobility as well as logistics, and potentially a future of connected autonomous vehicles (CAVs). Even if fully driverless cars are not imminent, by creating a connected infrastructure network, additional channels of more personalized communication and advice are available to both those managing the roads and those using them, which research suggests would be welcome and potentially more effective than existing road network channels, such as VMS (Chorus et al., 2006).

The wealth of big data has also driven the creation of new transport services, such as public transport that can vary routes and timetables according to demand, ride-hailing services, car clubs, shared bicycles, and electric scooters. Most of these vehicles produce a wide variety of big data from in-built systems that track the vehicles either continuously or at key nodes such as pick-up and drop-off points. They utilize digital platforms that enable customers to journey plan, book, pay for, and track their trips. The business models of these new transport services are often founded upon the volume and velocity of big data, which allows them to provide an efficient service even where demand is constantly shifting in space and time. The personalization of transport services is at the other end of the spectrum from the regularization and standardization that previously drove the collection of transport data and traditional transport service and infrastructure design. Thus, big data are the foundation for any "mobility as a service" (MaaS) business model.

Likewise, other big data sources in transport, such as journey planners, customer feedback channels, and transport applications designed to promote loyalty, rewards, fitness, social interaction, or status-sharing potentially have value in the development of future, personalized transport services. New transport services depend upon using tracking and feedback data from their customers to build their businesses. However, such data are more difficult to verify. Applications generate "crowd-sourced" big data from anonymous members of the public, who may plan a journey but not make one, share news of congestion or crowding that others

would consider a normal level of service for that route, or claim a journey made by a mode they did not take. Therefore, such data will have sampling and other biases that require careful analysis before being used to describe wider transport trends or issues or being applied to planning and strategy purposes. For example, commercial applications with a fitness market will not collect data on a representative sample of those who use active travel modes for utilitarian purposes, and privacy policies render contextual information such as journey purpose and socio-demographic profile unavailable (Romanillos et al., 2016). Still, big data with time-stamps and geolocations may offer useful insights into mobility, accessibility, and travel demand, particularly when linked to more randomized or validated locational data or where the volume of data points enable statistical methodologies to correct for certain biases.

Big Data from ICT Sources

Greater volumes of high velocity, volunteered geographic information are available from ICT sources, many of which have lower sampling biases than big data collected by the transport sector, yet have tremendous utility to generate insights about mobility. For example, mobile phones are now almost ubiquitous among the working adult population in many countries. Likewise, electronic financial transactions are more common than cash in some geographies. ICT sector data are not collected for transport purposes and cannot necessarily be linked to flows on the transport networks, and there are also various interpretive challenges in terms of spatial and temporal granularity. However, such data does have value for transport modeling and appraisal and for various strands of research into travel behavior, event management, accessibility/equity issues, and urban service delivery. Both transport and ICT data tend to be collected for operational or commercial purposes, not modeling and research, but there is speculation that ICT big data could offer similar or even more comprehensive intelligence at a lower cost. Issues around biases, however, and also conflicts between privacy/commercial sensitivity and the openness of data, mean this is far from certain.

Mobile Phones

Mobile phones have generated the most interest among modelers and researchers seeking big data from non-transport sources. Coverage can be close to population level, and CDRs are created automatically whenever a mobile phone is used to make or receive a voice call or text or, for smartphones, to download data. Further details automatically collected by the mobile operators include when a phone is switched on or regains signal, when it moves between clusters of cell towers, when it switches between signal generations, for example, 3G to 4G, and periodic checks on a device's location to ensure service. The sum of such logs are sometimes known as Mobile phone Network Data (MND). These records have timestamps, but provide spatial information at a scale dependent upon the density of the cell network, which is more granular in urban areas, particularly if any records on WiFi use are incorporated into the dataset. Although the phone may not be in use during travel, the data do provide a clear record of users' locations when not moving, from which movement can be derived. Places that are regularly visited for long periods of time, such as home and work are fairly straightforward to identify and validate. From such data, researchers derive aggregate commuting distances and patterns, CO₂ emissions, and the density of central business district workers drawn from particular neighborhoods in a metropolitan area (Becker et al., 2013).

However, there are substantial gaps in the data and purposes for which such data may not be suited. There may be no records made during shorter trips, particularly on foot, or during stops made as part of linked trips. The routes taken for rural trips will be less precise due to the less dense network of cells. In addition, there may be inaccuracies in matching trips to routes and speeds to modes. Although separating road from heavy rail can be accomplished with some confidence, it is much more difficult to separate and validate different modes used on local, urban roads, such as bicycle, bus, car, and taxi. Aspects like vehicle type and occupancy are also inferred, rather than surveyed directly, and assumptions about mobile network users must be made in order to scale up the data to population level. Finally, as data owners, mobile operators recognize the value of their big data and the importance of privacy to their customers, and therefore may charge for any use, and insist on anonymizing and aggregating or pre-processing their data at their discretion. Despite those caveats, the benefits of covering a larger geographical area and sample size, as well as capturing longitudinal rather than cross-sectional data, should not be underestimated. Other datasets, including socio-demographics, can both improve the analysis and reduce the gaps in this key ICT data source.

Social Media and Location-Based Services

While some datasets that can be matched to mobile phone data are derived from the transport big data, or from surveys and censuses, other ICT data also provide more spatially granular records of movements, through volunteered geographic information. Some users choose to have their social media posts geotagged, or they may agree to their movements being tracked in order to benefit from location-based services that advertise nearby amenities. Some applications provide both social interaction and location-based services through gaming or arranging meet-ups. Many of these applications incorporate Application Programming Interfaces or APIs, which provide open access to the big data generated in real time. The variety of this data matches its volume and velocity, as text, images, and various other content accompanies the timestamp and geolocation. Veracity is also in question, as GPS may be switched on and off, and such applications tend to be favored by younger, more urban, and more educated populations.

However, these data provide valuable channels for analyzing activity patterns and augmenting other data sources, including traditional surveys, which consistently underestimate the number of short trips made on foot and struggle to account fully for variable travel patterns. For example, using geolocation, rating, and “check-in” data on food-based activity places combined with transport big data on traffic congestion, one study was able to measure the temporal variability of the attractiveness and accessibility of such locations (Wang et al., 2018). Personalized ICT datasets also add value in terms of economic and social behaviors, as they can be used to provide newsfeeds and alerts, inform market research for the delivery of online access, nudge changes in travel behavior, and offer channels for feedback. Indeed, if the purpose of transport modes is to offer choices in accessibility instead of mobility, then online access should be included in the mix, and ICT data can be used for the direct measurements of Internet access, activity, and quality of service. Yet transport practitioners are rarely well-versed in the geography and geometry of ICT networks, and how, similar to road or public transport networks, they offer varying levels of service based upon where and when access is required over what type of connection and for what purpose. The overarching purpose is transfer of information, but ICT access is affected by the volume, velocity, and variety of data being transmitted, and understanding the structure and operation of ICT networks better is essential to effectively using either the datasets generated by ICT and online services or those generated by transport modes and their users.

Summary and Conclusion: Implications for Uncertainties

The study and sector of transport are subject to more change at the present time than they have seen for decades, due to new digital technologies, new transport technologies, an aging population, more flexible working patterns, and more extreme weather, to name a few. All these factors affect not only the supply of transport infrastructure and services, but also the structure of demand. In many cases, their impact on the future of transport is still uncertain. Previous assumptions regarding averaged travel patterns or routine maintenance regimes, based often on annual surveys, offer limited insight into a variety of potential futures and limited ability to respond robustly to systemic shocks. Yet big data have the potential to provide the spatial and temporal granularity to fill knowledge gaps, more accurately depict changing societies and environments, and prepare for an uncertain future. Big data might offer more insight into individual behavior, but using data science techniques can also provide insight into the resilience of human mobility more broadly, for example, during natural disasters (Wang and Taylor, 2016).

Big data from various transport modes and other sources can provide transport operators and managers with the means to improve the efficiency or safety of their networks. Transport modelers and policy-makers can achieve more variable and locally customized outputs from big data that offer more realistic representations of the transport supply or demand being assessed. These outputs can be translated into knowledge that can be applied to solve problems, make policy, or predict the likelihood of future scenarios. However, big data can only be successfully applied if transport researchers and practitioners have the resources and skills to manage the volume, velocity and variety of big data, and the understanding to appropriately question the veracity and improve the value of big data through linking with other traditional and emerging data sources. Regulation and statute has struggled to keep pace with the issues involved in the collection, storage, access, and analysis of big data. Data generators, both infrastructure and service operators as well as individuals using new transport and ICT services, have legitimate privacy and security concerns, while data holders or owners are concerned about commercialization and competition. Even as new digital technologies and methodologies make the use of big data possible, data do not become information until analyzed, nor intelligence until the messages derived can be communicated to an audience beyond the transport discipline or sector. Thus, this article aims to provide an introduction to transport modes and big data, and the risks and benefits of using big data to contribute to the future of transport study and practice.

Introduction

Transport matters for most aspects of life, and so tackling transport inequalities can be vital for a just or fair society. There are more forms of transport mode inequality than could possibly be listed. Yet perhaps not all inequalities matter, and even where they do matter, they cannot all be tackled. So priorities need to be determined. To make sense of inequality and transport we need some conception of why equality matters at all. This allows assessment of what transport inequalities are relevant, which trivial or unimportant, or even which would be required within a just mobility system. This in turn enables development of means of assessing whether there are relevant transport related inequalities in a given context, and if there are, what if anything, could or should be done to tackle them. Given this, the article is structured as follows. The next section begins by sketching a high-level conception of equality, which is sufficient to guide assessment of transport mode equalities, and then gives a narrative account of major forms of inequalities associated with transport mode. Following this, the second section considers approaches planners and researchers can take in assessment of inequalities related to transport mode in different contexts. The section outlines the rationale for assessment measurement and indicator. It discusses the challenges of formulating indicators and other assessment in ways which are feasible given available data and limited resources, but which do not lead to perverse outcomes in which relevant inequalities are overlooked, or where some inequalities risk being exacerbated. Finally, the third section presents considerations for tackling the complex, and interrelated forms of inequality, which can be created by transport use. As we see through this article, transport mode inequalities are frequently context specific, but there are some broad considerations, which can help guide efforts to reduce transport mode inequalities.

Why Transport Matters for Equality

Why Does Equality Matter?

A good starting point for assessment of equality is to ask “equality of what?” (Cohen, 1990). It is sometimes said that equality is about treating people the same. If there were no more to it than this, then it would not be a very helpful, or plausible concept, for assessing social and economic organization, or indeed for assessing other aspects of life and the way in which we treat one another. In the numerous theories of justice or fairness which exist and in which equality is central, the idea of equality is never given such a superficial meaning. A conception of equality common to many, although not all, theories of justice is that equality fundamentally matters because:

Each person matters, simply in virtue of being a person. This means that:

- their life matters and
- their quality of life and welfare matters.

This conception is compatible with most theories of distributive justice, including consequentialist theories, communitarian theories, and rights-based theories. As we would expect, interpretation of this conception differs within different theories, however, the conception by itself is sufficient to guide discussion of equality and transport modes. In this article we will use the conception rather than adopt a full theory, since prospects for consensus about the conception are far greater than those for consensus over any given theory.

Equality and the Benefits and Values of Different Transport Modes

We all benefit from the mobility system, whether or not we are actually traveling, since it is a vital component of systems of production, and distribution of goods and services. Yet, as is well recognized, there are enormous inequalities in distribution of those benefits, and this is one sense in which we see inequalities associated with use of transport. If each person matters, then of course we might say we are better off with the transport system than without it, however, this leaves a major question about whether and how changing the way in which we use transport could mean those benefits are more evenly distributed.

For individuals, families, and social groups, the ability to move around—and the ease and safety with which this can be done—can be crucial for possibilities of social and economic activities, including education work, organizing family and social life, for communities, for participation in society and politics, and for numerous other activities which people find valuable. It is worth keeping in mind that barriers to activities found in one part of life could have long far reaching implications: for instance, consider the implications if someone does not access to the transport they need for education. To assess how transport use can have a role in equalities in relation to these benefits of transport, we should keep in mind the number of points:

- First that mobility is not simply a matter of traveling in a vehicle, it can also be movement on foot, and this can be an important part of some social activities. In such cases motorized modes can actually be a barrier to mobility. We see this in [Appleyard's \(1981\)](#) famous study on social interactions between neighbors on lightly trafficked streets and those on heavily trafficked streets.
- Second that the transport modes required for similar types of activities depends on the built and natural environment in which people live and on other differences between people's priorities. So, people in densely populated areas with a safe environment for walking cycling, may rely far less on motorized transport for everyday activities and those in more sparsely populated areas. Recognizing this can be important for assessing equalities and transport, however the relationships are complex. We may need to question whether, or the extent to which, people can choose where they live and so can choose to have everyday lives which rely on differing transport modes ([Mattioli, 2017](#)). Further, as noted earlier, people are not the same and the sorts of activities in which they engage in are unlikely to be the same either: for some people organization of large families may be the priority, whereas for others it may be participation in public services or business, and for others something different again.
- Third that existence of transport is necessary but not sufficient to ensure that people can make use of it. To be usable, transport needs to be responsive to the variations in people's needs and circumstances. This means being physically accessible, available, and affordable. Physically inaccessible transport can create acute inequality with some people becoming socially and economically excluded. Partially accessible transport can also exacerbate inequalities. For instance, if people with disabilities need to make additional arrangements in order to be able to use transport, the time and planning required can place them at a disadvantage. An example is requirements that people with disabilities make arrangements in advance for assistance to use public transport ([Lawson and Matthews, 2005](#)). Severance, which can be caused by vehicular transport infrastructure with inadequate crossings for those using nonvehicular mobility can also be understood as a barrier to accessibility as it can leave people unable to participate in activities involving nonvehicular mobility, or can prevent people reaching and so using available public transport. Partial inaccessibility can also be caused where the rules for using public transport are not easily understood by people. Examples of this would be timetables that cannot be easily read, rules about ticketing which are complex, but which come with stark warnings about penalties for getting anything wrong, and poor information about public transport routes and about where to get on and off.

Availability of transport can be quite a straightforward matter of either owning or having access to private transport, having access to safe environments for nonmotorized transport, or the existence of public transport. Where people rely on nonmotorized transport or public transport, the most visible forms of inequality are associated with unsafe conditions and a lack of services. Even where some services exist, inequalities in people's ability to organize their lives and engage in social and economic activities can depend on the comprehensiveness of those services. Where relatively short journeys take a very long time because public transport services are infrequent or not well integrated then people's ability to engage in activities is reduced. Affordability of transport can also seem a fairly straightforward matter, however, in considering how transport affects equality we might need to take account of the possibility that people can pay for the transport they need but doing so can create other hardships. There is evidence of this in relation to car dependence, including a study indicating that some of those people living with what the European Commission call material deprivation nevertheless maintain ownership of a car. There is a correlation between those in material deprivation who own a car and those living in areas with poor public transport ([Mattioli, 2017](#)).

Risks and Harms of Different Transport Modes

Road Traffic Collisions

The [World Health Organization \(2018\)](#) estimate road deaths at around 1.35 million worldwide, a number which has increased since 2001, although there has been a small reduction in rates of death per 100,000 people, from 18.8 to 18.2 over that time (as the population has increased). As the WHO point out there are apparent inequalities in levels of exposure to risk of road traffic collision between countries, and within countries: In low-income countries the average rate of death is 27.5 per 100,000 population, whereas in high income countries it is 8.3 per 100,000 population. Further, there are variations in proportion of road deaths by mode used by the victim as a percentage of all road deaths. The WHO report that worldwide, on average, "pedestrians and cyclists represent 26% of all deaths, while those using motorized two- and three-wheelers comprise another 28%" and 29% are "drivers or passengers of 4-

wheeled vehicles" (2018, p. 6). The remaining 17% are described as "others" or "unspecified" because "data is not available or is incomplete" (World Health Organization, 2018).

Road traffic deaths and injuries are clearly a matter of concern, however, there is a more complicated question of how they raise particular concerns for inequality associated with transport modes. The high rates of deaths in road traffic collisions, and particularly the far higher rates in low-income than in high-income countries, suggest that the sorts of transport systems which exist are disadvantaging some people more than others. We might consider whether those at risk from road traffic deaths also benefit from the transport that they are using, but given the differences in rates of death associated with low and high income countries it seems difficult to sustain any argument that benefits are in anyway proportionate to the risks faced. The differences in proportions of road deaths by transport mode adds to this concern of inequalities. The proportion of road deaths for pedestrians and cyclists is actually (on average) slightly lower than drivers and passengers of four wheeled vehicles. However, to assess whether this really means there are not disproportionate risks faced by pedestrians and cyclists, we may need to consider what proportion of travel is done by different modes, and we may also want to consider what choice people have about the transport mode that they use. The reasons for suggesting these considerations follow from recognition that people need to travel in order to get on with their lives, and that there are differences in the choices or control that people have over the transport which they use (see above). Yet while we can quite easily, assuming we have the necessary data, compare rates of death on the roads as proportion of a population, the metric for assessing inequalities in risk by transport mode is not straightforward. Should we judge rates of risk according to distance traveled, or according to the number of trips made, by some other method such as length of time spent on the road (Mullen et al., 2014)? If we look at distance traveled as the metric for risk, then we are arguably taking account of people's need to travel certain distances, and of how people may have different levels of choice over the transport they can use. However, we may be overlooking the possibility that some people need to travel further distances in order to go about their activities (again see above). If we look at number of trips, we may be taking account of differences in the distance that people need to travel, but we may still miss the possibility that some people need to make more trips in order to get on with their own lives and contribute to society. Finally, if we look at length of time spent on the road, we might consider whether we are that we are not giving too much account to the risks faced by people in just one part of their life, that is, the part when they are traveling. However, if we use this metric to inform policy interventions seeking reduce inequalities and risks from collision associated with transport mode, it will imply that the policy should focus on safety of those who traveled at high speed rather than on pedestrians or cyclists. The reason for this is that the level of risk/time spent traveling is much higher for a person facing a 1 in x risk of death while traveling 1000 km at 90 km/h on average, compared to one facing the same 1 in x risk of death while traveling 1000 km at 15 km/h. We can question whether this policy focus would be justified by a conception of equality motivated by recognition that each person matters equally. There are further, instrumental reasons, for considering policy responses to different metrics for assessing inequalities in exposure to risks on the roads, and these will be considered in the following sections.

Pollution and Land Use

Poor local outdoor air quality from pollution including nitrogen dioxide, particulate matter, a large proportion of it coming from transport (a proportion which differs in different countries depending a range of factors such as other industrial practices) is held responsible for over a million deaths each year worldwide (World Health Organisation, 2016). Understanding of the relationship between such pollution and health is something which is increasing over time. As more evidence emerges, estimates of deaths attributed may change, as may understanding of the forms of ill health associated with this pollution. The mortality and morbidity attributed to this pollution include excess deaths from cardiovascular problems; it is also found to be a cause of lung cancer (International Agency for Research on Cancer, 2016). Transport pollution can create inequalities as some people's health means they are at greater risk than others risk of suffering from transport pollution. There are also, in some places, correlations between exposure to transport pollution and the levels of households living in poverty (Barnes and Chatterton, 2016).

Along with poor air quality, certain transport modes are associated with noise pollution (Kaltenbach et al., 2016), and there will be inequalities in exposure to this pollution which are associated with proximity to the use of those transport modes. So those living close to busy roads, or near to airports maybe particularly affected. Finally, the land taken for different types of transport infrastructure can have implications for people's lives, and for inequalities. We have already outlined how infrastructure favoring some, especially motorized, modes can have implications for the ability of people to use other, especially nonmotorized modes. Beyond this we may need to consider inequalities associated with compulsory land purchase, or the changing use of what was previously common, or unowned, land for transport infrastructure.

Climate Change

Fuel combustion for transport is responsible for just under one quarter of carbon dioxide emissions worldwide (International Energy Agency, 2018). The evidence of the need to rapidly decarbonize is widely recognized (Intergovernmental Panel on Climate Change, 2018), and there is increasing attention on transport as one of the sectors with a particularly poor record in contributing to decarbonization, with failures to sufficiently improve emissions from, and to reduce demand for, motorized vehicles. In some countries, such as Britain, where there are statutory requirements to decarbonize, levels of carbon from road traffic actually increased slightly over the period 2013 to 2018 (Committee on Climate Change, 2019). There are acute concerns about the implications of climate change for the lives and livelihoods of people across the world now and in future. There is a wide body of work, which indicates that the harm of climate change is unevenly distributed, with less wealthy countries and people being particularly vulnerable.

Assessing Inequalities Associated with Transport Mode

The last section considered how transport modes can be associated with a range of inequalities. What that section also indicates is that understanding those inequalities can be quite a complex matter, requiring us to simultaneously take account of a range of factors (such as the level of choice people have, or benefit that they gain from different transport modes), and where there is scope for discussion about exactly how these different factors should be considered. In that discussion, numerous correlations were used to indicate where we might find inequalities, such as between the levels of road deaths by mode as a proportion of all road deaths. Those correlations do not by themselves tell us the nature of the inequality, and may actually not be revealing a relevant inequality at all, but what they do is suggest where to focus attention. We can add that the correlations can only be identified if the relevant data are collected, so we should keep in mind that we may be missing relevant inequalities due to lack of data. Further, if we are to use an understanding of inequalities associated with transport mode to inform policy, we may need, in addition to a narrative accounts of inequalities, indicators which can be used to illustrate levels and types of inequalities which currently exist, and to inform debate and development of interventions to reduce those inequalities. In other words, there may be a need to make some simplifying assumptions for indicators, but to do this in a way which does not lead to perverse consequences such as missing important inequalities, or creating new inequalities through the use of the indicators to inform policy.

In the rest of this section we briefly outline three examples of methods for assessing transport mode inequalities, and indicate questions which each of these assessments might raise for policy interventions to reduce inequality. One type of indication of transport mode inequalities comes from looking at either the absolute number of trips made by different social groups, or differences in trips made by different mode, particularly by private motor vehicle or by aviation. Given the discussion earlier, we can see that care needs to be taken in drawing inferences about inequalities from the number of journeys made, or the modes used since people have different travel needs in order to fulfill similar sorts of activities. Nevertheless, where we see large variances between journeys or modes used by different social groups, we might investigate whether there are underlying inequalities in opportunities to engage in a diverse range of activities. For instance, are there some groups who are, and some who are not, able to experience international leisure travel or to benefit from international a long-distance business travel ([Banister, 2018](#))?

Second, we can consider correlations between households in poverty and exposure to transport pollution. If we accept that each person's life is equally important then there is little doubt that this is a concern for equality. It has been argued that this form of inequality may be further exacerbated because of evidence that those who faced the higher levels of exposure to pollution are not the ones creating that pollution and so are not directly benefiting from the travel, which creates the pollution. The further question this raises is about who is responsible for this additional inequality—does the responsibility rest with the transport users creating the unequal levels of pollution or does it rest with transport planners and society more widely? If the former, then it might be used to justify measures which restrict or impose additional costs on transport users. Yet if it is the latter, then imposing burdens on the transport users may create further inequalities if those transport users have little option but to use the transport they do.

Accessibility, understood as a measure of the time taken to get to key services or employment from different residential areas and by different transport modes is a prominent method of assessing the extent of transport related social exclusion and inequality ([Martens, 2016](#)). This method recognizes importance of transport for social and economic activity and so for people's lives and welfare. It also takes account of the opportunity cost of having to make time-consuming journeys for everyday activities and it recognizes that not everybody has the same ability to use different transport modes. Yet, looking at this form of accessibility alone leaves open a number of questions for equality. One set of questions surrounds the nuance of the measurement, for instance, does it take account of the frequency of public transport, or the quality and safety of the environment for walking and cycling? Further, if it is used to inform policy we may also need to consider the quality of the services or employment at issue (cf. [Guimarães et al. 2019](#)), and whether actions which focus on access to these services could lock in relative inequality with certain groups of people being excluded from opportunities because of where they live or the transport modes to which they have access.

Tackling Inequalities Related to Transport Modes

The discussion of the previous two sections emphasizes that transport mode inequalities can be highly context dependent, involving questions such as the extent to which the local transport system enables travel by different modes, the extent to which people have the option to live in areas which are accessible by different modes, and questions about proximity to transport infrastructure and associated pollution. We can however make some broad points about approach ([Table 1](#)).

One approach to tackling inequalities is to prioritize those which are most acute. This could mean, for instance, a focus on removing severance which prevents people from participation in social and economic and other activities, and which therefore creates more severe inequalities than those which occur when people can access activities but where doing so is awkward. Beyond this is a case for policy responses, which recognize that there are multiple forms of inequalities related to transport modes, with some relating to the benefits of transport and others to the harms of transport. Tackling transport mode inequalities will tend to require attention to these multiple forms. [Table 1](#) offers a short guide to this assessment, and shows that while there is complexity, there are also common questions which can be asked in relation to measures intended to tackle different types of inequality (a more detailed guide is given in [Mullen et al. \(2014\)](#)). This can already be seen in the discussion above, for instance in relation to the question of whether equality would be served or harmed by measures which impose burdens on motor transport users in order to reduce pollution. A similar concern can arise if policy focuses on tackling pollution primarily through promotion of cleaner vehicles. Even if

Table 1 Overview of guide for assessment and policy intervention to tackle transport mode inequalities

Assessment of inequalities		
	Benefits of transport	Harms of transport
Considerations: identify inequalities	Differences in activities involving transport which are im/possible. Include time taken to travel Physical accessibility and affordability of different modes: time taken to travel Severity of exclusion: for example severance	Risks of death and injury in road traffic collision by mode/trip and mode/distance traveled Levels of pollution and difference in exposure
Responsibility: collective or individual?	Degree of choice about modes used: include safety	Carbon dioxide emissions Degree of choice about modes used: include safety: includes questions about what a reasonable level of welfare consists in
Assessment of policy intervention to reduce inequalities in availability of transport		
	Benefits of transport	Harms of transport
Considerations	Implications for availability and affordability and accessibility of transport modes: include consideration of severance	Absolute levels and inequalities in risks of death and injury in road traffic collision by mode/trip and mode/distance traveled Implications for pollution including carbon dioxide emissions, and distribution of exposure to transport pollution
	Degree of choice about modes if the measure imposes costs on individuals	
Assessment of policy intervention to reduce inequalities in harms of transport		
	Benefits of transport	Harms of transport
Considerations	Implications for availability and affordability and accessibility of transport modes: include consideration of severance	Absolute levels and inequalities in risks of death and injury in road traffic collision by mode/trip and mode/distance traveled Implications for pollution including carbon dioxide emissions, and distribution of exposure to transport pollution
	Degree of choice about modes if the measure imposes costs on individuals	

we set aside matters of affordability of cleaner vehicles (perhaps through subsidy), such an approach can still leave inequalities which are created by high levels of traffic—these include difficulties for pedestrians and cyclists, and therefore difficulties in undertaking activities involving walking or cycling such as neighborhood social activities (Mullen and Marsden, 2016).

Addressing multiple forms of inequalities at the same time might be supported by consideration of the extent to which we can prioritize transport modes associated with creating fewer inequalities. This is the case for walking and cycling, which impose relatively few risks from road traffic collisions, and which create little pollution, and take up relatively little space and so have relatively little burden on land use and congestion. Taking this approach helps to guide policy responses to inequalities. For example, as noted in the first section, while pedestrians and cyclists impose fewer risks in collisions they do face proportionately high risks. One type of policy approach for improving pedestrian or cyclist safety could be through measures which restrict walking or cycling (perhaps through prohibitions on walking or cycling on some routes, or insisting that pedestrians and cyclists use road crossings which increase journey length). But this approach might be counterproductive in tackling wider inequalities including those associated with transport pollution, climate change, and with high levels of traffic creating barriers or severance for use of other modes.

Summary and Conclusions

Assessment of inequalities relating to transport modes, and planning aimed at reducing those inequalities, should have embedded within them a conception of why equality matters. Without such a conception which can guide responses to the question “equality of what” we have little basis for determining whether we should be concerned about any (or all) of the multiple differences in how people use or are affected by different transport modes. Perhaps more importantly we risk arbitrarily privileging some inequalities—and the interests of some people—over others. For instance, we can risk focusing on accessibility or affordability at the expense of addressing health inequalities associated with exposure to transport pollution. If transport inequalities matter because each person

matters, then it follows that we should be concerned about inequalities associated with the ability to travel and so engage in social and economic activities, and simultaneously have concern for inequalities associated with transport pollution, carbon emissions, and collisions. Yet while assessment of transport mode inequalities might be unfeasible without a conception of equality and why it matters, it remains difficult even with such a conception. The nuance and complexity of many of these inequalities raises finely balanced questions for assessment: for instance, we may have concerns that users of active modes do not face higher risks of harm from road traffic collisions than do car occupants, but it is more difficult to determine what metrics should be used to compare those risks. The picture is further complicated when we try to take account of the extent to which people can be said to exercise choice over forms of travel and mobility that they use. While questions about the nuance of assessment are a work in progress, we can make some broad comments about the sorts of approach, which might be required to tackle transport mode related inequalities. The need to simultaneously consider multiple aspects of inequality makes the case for looking to measures which will bring cobenefits across those different aspects. Much of this is the bread and butter of sustainable transport, including a focus on active travel and affordable and accessible public transport. Yet concern with inequalities points to particular ways of making decisions concerning these measures, for instance emphasizing the case for prioritizing the reduction of severance since this can be a cause of acute inequality, and focusing on implementation of active travel or public transport measures which prioritize inclusion.

Biographies

Dr Caroline Mullen is a Senior Research Fellow at the Institute for Transport studies, University of Leeds. Her research and publications focus on sustainability and mobility justice, especially on the relations between mobility justice and wider equalities and social and environmental sustainability. She also researches transport governance, policy and politics of mobility planning and carbon reduction in transport, and active travel. Her research uses theoretical analysis and primary and secondary social research methods, including innovative methods such as mobile interviews and citizen and expert deliberation. Much of her research has included collaboration and engagement with public and practitioners including transport planners from across Europe, third and private sector actors. Please see <https://environment.leeds.ac.uk/transport/staff/966/dr-caroline-mullen>.

Introduction

Railway traffic management pertains the most efficient usage of railway resources (infrastructure, vehicles, crew) in order to deliver the best possible service for operators and passengers, despite unavoidable disturbances from planned conditions. Its relevance relates to the need for better exploiting the limited, expensive resources needed to run railway services. The key idea is the exploitation of some flexibility in planning, by suitable online control and optimization, when a given evolution of the system in the future can be estimated. Therefore, railway traffic management is applied at different time scales. This contribution describes, in order: background on railway traffic management; general description of needs and constraints of railway traffic; the time scales of flexibility, and degrees of control, which could be exploited; examples identified from science and industry; some mathematical foundations and pointers for the most relevant problems; and an outlook and research needs.

Background

Railway traffic has been a key enabler of economic growth and transport performance for more than hundred years. Its advantages against private traffic are still evident in terms of transport capacity (passengers or freight transported in unit of time), speed, dedicated infrastructure connecting point to point cities and places of interests, space capacity (passenger or freight transported per vehicle length, infrastructure length, infrastructure width), energy efficiency, high reliability, very high safety, as well as costs. Typically, railway traffic is organized in lines providing transport services to passengers, interconnected over a specified network to fulfill transport demand by people or goods (Monzon and Lopez, 2020).

A railway network relies on an effective coordinated usage of a set of resources, including infrastructure asset (tracks, stations), vehicles (trains, locomotives), human resources (drivers, staff), energy and control/monitoring (Hansen, 2020). The broad concept of railway planning scheduling and management targets efficient allocations of such resources, at different time scales, and involving different stakeholders. Currently, it is accepted that the challenging capacity increase targets for railway systems identified by policy makers can only be achieved through intelligent use of the existing rail infrastructure and efficient use of the available transport capacity. Moreover, the possibility to adjust to very fast-changing situations (software) is a peculiarity of the management, in contrast to building new infrastructure and purchasing new vehicle (hardware).

General Description

The mobility needs of people and goods are represented as a **transport demand**, whose precise knowledge is a major challenge in transportation studies (Patrizia Franco, 2020). Trains are operated to fulfill this demand, bundled in lines. For a detailed description of infrastructure planning, stop planning, and line planning, see (Nielsen et al., 2005) and (Profillidis, 2020).

Train vehicles operate on railway networks. Differently from car or buses traffic, unsafe movements of vehicles are intrinsically forbidden, by means of a signaling and safety system that detects train positions, and determines safe zones where any vehicle can move (movement authority). Those movement authorities relate to a minimum safety separation between trains; a key concept is the block section, an infrastructure part that is assigned exclusively to at most one train at any one time.

Train movements can be modeled by a set of **characteristic times**, as follows. The running time of a train through a block section starts when its head (the first axle) enters the block section and ends when the train passes the end of the block section. Typically, railway operations specify heterogeneous traffic sharing the available capacity; this leads to challenges as the different services have very different speed, and stopping policies. Safety regulations impose a minimum separation between consecutive trains traveling through the same block section, which translates into a minimum headway time between the start of the running times of two consecutive trains on the same block section. This time depends on the length of the block section and (among others) the speed and length of the trains, including the time the entire length of the train gets out of the previous block sections, plus time margins for dissemination of information (signal) to the driver. The interaction between two successive trains moving safely over the infrastructure can be studied based on the blocking time theory (Hansen and Pacht, 2014), determining how much time must pass between two successive trains, depending on their characteristics, to have safe and smooth operations.

The effective usage of railway systems is normally related to a **timetable** (a schedule of operations), which can be computed (months) earlier than operations and/or possibly updated very shortly before operations. The timetable specifies the time at which trains are arriving at departing from any planned station and relevant point. A train is not allowed to depart from a stop before its scheduled departure time and is considered late when arriving later than scheduled. At a platform stop, the scheduled stopping time of each train is called dwell time. Generally, the frequency between successive services of the same type is relatively large, which reflects on demand satisfaction. Transfer connections with a minimum synchronization time enable a smooth continuation of a trip of the same passenger across two different services.

Disturbances affect rail traffic. Traffic perturbations have small magnitude and extent; (e.g., longer dwell times, headway conflicts, passenger connections, or technical failures); and disruptions are more substantial modifications of scheduled train speeds and routes, requiring strong changes to service. In both cases keeping the traffic running to fulfill the transport demand requires changes to the plan. In general, very little can be done against exogenous delays, triggered outside the railway systems (primary delays: i.e., failures, interaction with persons at stations or along tracks, longer dwell time, bad weather).

Railway infrastructure has normally very limited possibility for overtaking, typically only at major stations, for cost reasons, and infrastructure efficiency. This results in delays being propagated between successive trains as consequences to route conflicts. A route conflict occurs when the movement authority of a train is restricted by a preceding train, that is, a train meets a restricted signal and must prepare to stop before a stop signal protecting an occupied block section, increasing further its delay. **Knock on (or secondary) delays** represent this domino effect of increasing disturbances, which reduces seriously the quality of the service offered.

The process of updating the schedule when new information is available defines the railway traffic management. The timetable is updated into a **disposition timetable**, where train distance headways are respected, and the current delays are considered and reduced.

Time Scales and Degrees of Freedom of the Different Problems

A **service intention** is a concept specifying the frequency, the amount of train runs on a line to fulfill the customers' needs, and a description of departure, arrival running times but without specifying too precisely what operations should be (Caimi et al., 2011). The term "intention" refers to the envisaged operation, while not being yet sure if the offer is feasible or happening in a very precise manner. Service intentions are systematized into periodic offers running almost regularly throughout the day, to facilitate the use of public transport.

The **timetable** consists of the "production plan" of the service intentions, scheduling the detailed resource assignments, that is, departure and arrival of all services, and time supplements for delay avoidance and/or recovery (Caprara et al., 2002), in order to:

- maximize performance indicators attractive to customers, and maximize the trains load;
- match travel demand patterns including peaks;
- secure headways between train services to make them resistant to delays; and
- synchronize the arrival and departures of different lines, for smooth interchange at major stations.

The determination of a timetable requires the interaction of many stakeholders (authorities, train operators) currently done by human planners; automated timetabling computation showed great potential, especially for incremental adjustments or computation of variants (Kroon et al., 2009).

Most railway networks are operated based on a **periodic timetable**, that is, the services repeat themselves after a certain period of time (e.g., an hour). This allows passengers to remember better the available service. Full periodicity deals badly with peaks of demand in rush hour, often requiring additional services. To determine a periodic timetable, the time horizon is restricted to the period only; but the complexity is increased by the enforced periodicity. Specific types of timetables have symmetry axes, or symmetry axes for some train line along a specific time point, which occurs at stations. When this is the case of multiple train lines, it is possible to structure a pulsed timetable, where most services arrive at the station just before a critical pulse moment, they are simultaneously at the station, and leave all shortly after the pulse time. This enables smooth transfer connections within a large set of trains, thus enabling practically faster transport chains, at the expense of large infrastructure requirement at stations needed for the pulse moment.

A key characteristic of a timetable is to remain performant also against delays. To this end, **robust timetables** include running time supplements and buffer times to absorb minor deviations from nominal characteristic times. Some capacity is traded off to time

reserves increasing reliability. Larger disturbances that a timetable can cope with without major adjustments require larger time reserves, thereby decreasing capacity available for traffic. A higher volume of traffic results in very high sensitivity of train operations to perturbations, resulting in instability with even minor disturbances hindering the adherence of the actual traffic to the expected plan.

The determination of platforms at stations, (**platforming**) and routes (**routing**: sequence of block sections, that trains follow to reach a destination station starting from an origin station) is sometimes included in the timetabling stage, in an integrated manner (computationally hard), or in a sequential manner (prone to sub-optimality). Rostering is the tactical process (horizon of one or few weeks) of **assigning specific vehicle and personnel** to the running trains and services, based for instance on forecasted passenger flows.

Real time traffic management strategies (other names used in the literature including: dynamic traffic management, dispatching online, railway traffic control; train conflict detection and resolution) exploit buffers and margins in the timetable to steer the system towards a desired state. Once a perturbation is manifest, control actions such as changing and adjusting running times, dwell times, departure times, train speeds as well as train orders and routes are implemented by traffic control managers within seconds or minutes. The goal is to keep good performance and reduce the propagation of delays in the network (Cacchiani et al., 2014; Corman and Meng, 2014). The real time railway traffic management is the ideal required complement of a service intention, that is, improves performance by exploiting the details not fixed in the plan (or, available for change in the real time operations) by control decisions which are based on the precise ever changing situation, in real time. This approach requires effective and fast traffic control procedures by either human dispatchers, or automated systems based on mathematical optimization.

The running time of trains can be updated (**retiming**) by resulting in updated arrival departure time at stations, while keeping fixed train orders and timetable structure. Trains can follow the updated advice by route setting and signals prescriptions, or more sophisticated driver advisory systems, including speed-space-time goals (so called Train Path Envelopes); or even automated train operations directly implementing the computed prescriptions (Wang and Goverde, 2016).

Reordering or rescheduling has instead a view over multiple trains, and updates orders of trains. Similarly, **rerouting** changes their route. Both actions have a greater potential for reducing delay propagation, allowing to exploit the available infrastructure capacity in the space and time where/when it is available. Some of those choices might have impact to passengers (i.e., cancelled stops, different running time, different platform at stations). Most often, when changing orders or routes, those decisions must be communicated opportunely to passengers, so that they can board the most convenient train in the updated disposition timetable.

When disturbances are of particularly serious intensity, train services and lines need to be substantially changed (**reservicing**), resource plans updated, new train routes have to be followed, short-turning or even cancellation of services applied. In such cases, the entire structure of the offer is modified, partially dropping the planned timetable, but still with the goal to match the service intention, as much as possible (Binder et al., 2017). The challenge is the evaluation of such situations, which require specific modeling of very limited infrastructure capacity; multiple objective functions, representing the many stakeholders involved, including the passengers; dissemination of the right information to train managers and passengers.

Examples of Flexibility in Planning Which Can be Exploited by Real Time Railway Traffic Management

The most common objective function for railway production is punctuality, defined as trains reaching their destinations (or control points) according to the planned timetable plus a given threshold (say 3 minutes). While punctuality is specific and measurable, more comprehensive indicators relate to precise delays of trains. Both punctuality and delays do not measure exactly what customers want, that is, reaching their destination on time and with a high reliability, and not caring per se about just train delays. To this extent, planning flexibility can be exploited, to match the service intention to a new plan specifically addressing the contingent situation.

A timetable with strict arrival/departure times can be replaced by **flexible time windows** of [minimum, maximum] arrival/departure times at each platform, which enable some flexibility to be later exploited in a real time stage. The operational timetable (for railway operators, with explicit flexibility) therefore differs from the public timetable (for passengers, only the maximum arrival time and the minimum departure time). The longer travel times would be compensated by a higher reliability of train services. Similarly, a service intention can result into an imprecise timetable, with provisional, possibly infeasible train separation and/or orders resolved every day according to the precise conditions in real time. This flexibility allows to reduce delays if (possibly different) good schedules can be found within strict time limits of computation. Finally, a service intention can specify **imprecise description of stopping platform**, typically limited to the two sides of the same platform island; the final choice is left to real time traffic management. Similar options can describe routes outside stations.

The **delay management** problem focuses specifically at keeping or dropping passenger connections in presence of delays. If a connection is kept (i.e., train is held at a station waiting for a feeder train) there can be substantial passenger travel timesavings against the case in which a connection is dropped, reducing delays for trains, but increasing it for the passengers. Often, demand is considered known, without elasticity, sometimes described as Origin-Destination pairs. Due to the combinatorial complexity of the problem, limited details of the infrastructure are kept. Recently the inclusion of precise management of infrastructure and description of passenger-oriented indicators has been shown possible (Corman et al., 2017).

Mathematical Models for Railway Traffic Management

The mathematical models used for railway traffic management can be classified into few broad families. Time continuous approaches report time variables in a continuous domain. Time indexed approaches allow time variables to have only a few possible values, that is, an integer (often considering a minimum time resolution, say 1 minute). A different classification regards the **time resolution** and **space resolution** considered: macroscopic models consider link and stations as infinite capacity resources. Microscopic models represent block section as resources with unitary capacity, used in sequence, resulting in much larger sets of constraints and variables. Mesoscopic models somehow provide hybrid solutions between the two cases. Regarding degrees of freedom, the **inclusion of speed control** relates to continuous variables, and quadratic relations between speed space-time, resulting in non-linear programming models. The inclusion of train orders and traffic requires binary constraints due to the determination of which train must occupy in which sequence the infrastructure elements. The determination of which connection to drop or keep also relates into similar binary constraints. This is solved by means of integer programming approach or mixed integer linear programming approach, MILP (see for instance, [Cacchiani et al., 2014](#); [Corman and Meng, 2014](#); [Pellegrini et al., 2014](#); [Meng and Zhou, 2011](#)). Finally, **inclusion of passengers** desires and routing might take the simpler way of schedule based deterministic assignment, or stochastic assignment. Competition between different passenger groups complicates further the problem and requires behavioral assumptions.

Most railway traffic management problems can be **modeled** and formulated along a **timed event graph**, in which nodes represent events in time and space (possibly with associated services/ trains, resources) and arcs represent relations between them (such as precedence relations, durations). Models based on job shop scheduling with additional constraints (no-store and no-swap) have been relatively popular ([Mascis and Pacciarelli, 2002](#)), and termed **alternative graphs**, as the key decision is the alternative possible orders of trains over shared resources (block sections). Most microscopic approaches combine the blocking time theory for the recognition of routing conflicts, and a general discrete optimization model to evaluate possible solutions of train retiming, reordering, and rerouting against a specified objective function.

The **passenger assignment and guidance** is the problem of computing and disseminating a route advice to passengers (guidance), and evaluating the results of the actual route they took. In practice it can happen that the advice can range from complete and correct, to incomplete, imprecise, or impossible, especially under disturbances. More research on the interaction between information and route choice has been done in the general transit literature, identifying frequency-based transit assignment, and hyperpaths concepts. Currently, route advices are made available to passengers by online applications and websites, or by personal construction of a plan when looking at printed timetables at stations.

In typical railway networks, passengers have **free route choice** (within some boundaries given by a fare system) ([Freijnger and Zimmermann, 2020](#)). Thus, passengers might react to reordering decisions taken in the interest of minimizing their delay, by finding the path of minimum travel time. In theory, a system optimum (minimizing globally passenger travel time) might not correspond to a user equilibrium (a situation where nobody has incentive to take a different decision); the incomplete information of future events makes the situation even more complex.

Few approaches have been tried successfully in real life, able to **connect railway traffic management decisions with expected passenger reactions** and outcomes. For instances transfer connections should include the reaction of passengers to dynamic railway traffic management actions, even though those are still unknown at the planning stage. In such perspectives, static passenger flows are used, sometimes including realistic behavioral assumptions. Some data on past operations is utilized to compute distributions of delays and travel times. Even though more advanced data-driven deterministic models are able to explain a large percentage of process time variability using the values of explanatory variables, a certain degree of uncertainty, especially for dwell times, remains unresolved. The usage of such models in a real time perspective is still in its infancy.

State of Industry and Application of Railway Traffic Management Concepts

Basic dispatching systems have been developed to aid traffic controllers, whose computer support is often limited to graphical interfaces and simple automatic route setting systems, triggered automatically if a train approaches a signal according to the plan. The usual policy still consists of scheduling trains following their order in the timetable, or according to pre-determined dispatching rules, with few manual modifications actually considered. Experienced dispatchers have developed strategies which allow them to foresee simple forms of possible disturbance and their effects in advance, and to take compensatory control actions based the information they might have. Existing support system for dispatchers rarely go beyond monitoring the situation, as they provide acceptable solutions only for small-scale problems or for simple perturbations. Some simple implementations exploit flexibility in orders or platforms choice by first-come-first-served rules on those resources. They found their application in bottlenecks (e.g., underground stations such as Schiphol Airport in the Netherlands); moreover they are sometimes complemented by more sophisticated approaches able to determine a minimum look ahead in the future results of current decisions.

For larger delays, priority rules for different classes of train types are used, but cannot quantify the gap from an optimal network solution. For very large disruptions, operators often have prepared on beforehand a set of possible alternative timetables, which can then be adapted and implemented for the specific situation encountered. The path for implementation of automated real time railway traffic management systems has been started with a few implementations ([Borndörfer et al., 2018](#)); and demos of closed loop control systems ([Corman and Quaglietta, 2015](#)).

One of the best examples of the potential for automated and optimized approaches is showcased in the Dutch example (Kroon et al., 2009). The use of advanced operations research techniques for timetable, vehicles, and crew scheduling, lead to large benefits to the main railway operating company of the Netherlands, NS. The resulting yearly profit could be quantified in millions of Euro, achieved directly by cutting expenses or by increased passenger demand and punctuality bonuses for improved reliability of operations.

Future Outlooks

In the forthcoming decades **railway transport is expected to face a significant growth** of traffic flows, which will mostly have to be accommodated over the existing infrastructures. An increase of capacity utilization is needed to avoid reduction of reliability and punctuality of transport services. To remain competitive in a market with increased competition due to disruptive technologies and uncertainties, continuous economic and performance improvements are required. The last years have seen in general an increase in transport performance (passenger kilometers and ton kilometers) against a generally increased transport demand, by which ultimately the relative mode share of railways is often reducing.

More comprehensive **inclusion of passengers** into the problem will finally enable to directly target the passenger wishes, and not only the operator requirements. The interplay between assigning the passenger flows and generation of the schedule can arise at different levels, which has not been studied in detail so far.

A reason for online control also includes **major disruptions**, i.e. blockades, trains or facilities out of control. These situations require major changes in the train service provided, including canceling partial or full train services. The approaches should consider explicitly information availability, and the impact of very large delays towards the users, rather than immediate small delays of a transport link.

Technological developments currently allow **higher autonomy and controllability for most train operations**, by means of pervasive automation, depending on conditions of infrastructure and traffic. Having the possibility to control trains with very small margins and high reliability leaves further space to increase traffic at network level; and include other relevant objectives, for instance minimize energy usage (De Martinis and Corman, 2018).

The computational complexity of automated decision support for (real time) railway traffic management typically restricts the application to small cases and few possible degrees of freedom. On the other hand, the largest benefits are in large cases and simultaneous inclusion of multiple degrees of freedom. To this end, **decomposition approaches** in sequential, integrated, or iterative approaches are promising techniques.

The widespread use of **data analytics** enables opportunities for improvements of railway operations. This certainly includes forecast the future operations, by means of black box approaches, or explicit mathematical models. Stochastic prediction and optimization models attribute each event with a probability distribution in order to describe the uncertainty of its realization. Most delay analysis is now done a posteriori, or to estimate delay distributions when designing a timetable. Instead, dynamic models for real time prediction or management would be updated in real time as new information becomes available.

Summary and Conclusion

In summary, railway traffic management is a promising way to complement by resource optimization (software) the (hardware) potential of a railway system, which is typically resource-intensive and infrastructure-heavy. The current trend in railway operations goes decisively towards a widespread usage of such technologies. Their application has been estimated in academic studies, or already proven in industrial applications, to improve cost efficiency and quality of service over a range of time scopes and problems, for passengers and operators.

Introduction

The main components of indoor transportation (sometimes also referred to as Building Transportation) are elevators (also referred to as Lifts in the United Kingdom), escalators and moving walkways (also referred to as passenger conveyors). These components address both vertical as well as horizontal transportation.

This article presents a concise introduction to indoor transportation. It looks at the main five disciplines that comprise the science of indoor transportation. It then looks at the components and principle of operation of the most widely used elevator, the roped traction elevator. A high-level overview of the topic of elevator traffic engineering is then presented. The components of elevator space planning in buildings are presented, highlighting its close dependence on the capacity and rated speed of the elevator. An overview of escalators is given in the following section as well as moving walkways in the following section. The article concludes by discussing the modern developments that have been introduced in the last 30 years and that have transformed the sector of indoor transportation, as well as future developments in this area. The article concludes with a summary and conclusions section, that includes recommendations as to the most pressing areas of research.

For more detailed information on indoor transportation, readers are referred to the following references: [Hirscher \(1987\)](#), [Strakosch \(1998\)](#) and [CIBSE \(2000\)](#).

Historical Background

In the year 1853, Elisha Graves Otis (1811–61) demonstrated the safe operation of the roped elevator system in the show in the New York World's Fair. This invention made the safe use of roped traction elevators possible in buildings, by protecting the passengers from the risk of a falling elevator if the suspension ropes are cut. The demonstration gave the public the confidence to use roped-traction elevator. Elisha Otis went on to form what today is known as the Otis elevator company.

The basic concept of using suspension ropes to move the elevator car up and down in order to move passengers has remained unchanged for the last 150 years, despite many technological developments in terms of electrical motors, drive systems, control systems, and safety features.

Elevators have basically transformed the modern city landscape by making the concept of a high-rise building or a skyscraper possible. It inverted the concept of the office hierarchy whereby the higher management started to occupy the top floors in the building because they became the more desirable floors, with the lower ranks in the company employing the lower floors ([Harford, 2018](#)). By making the concept of the skyscraper feasible, it made it feasible to have high density populations concentrated in city centers.

Introduction to Indoor Transportation

When considering indoor transportation systems, a number of disciplines are relevant. It is thus important to distinguish between the following five disciplines:

Passenger Flow: This discipline involves the analysis of passenger (pedestrian) movements within the building mainly in the vertical dimension (although horizontal movement is sometimes considered simultaneously as part of integrated passenger flow studies in buildings). Readers who are interested in gaining a deeper insight into the area of human pedestrian flow in general are referred to the important book by J. J. Fruin (Fruin, 1987), as well as Chapter 2 of the CIBSE Guide D, 2015 edition (CIBSE, 2000).

Traffic Engineering: This discipline is concerned with the analysis of the expected vertical passenger flows in the building (usually referred to as Demand) and the sizing of suitable elevator systems that can meet such demand ((Barney and Al-Sharif, 2016), (Markon et al., 2006)). The selection process entails the specification of the number of elevators, their rated speeds and rated capacities.

Electrical Engineering A, Control Systems and Safety Devices: This discipline involves the use of electrical technology for the logic control of elevators, such as the registration and allocation of landing and car calls, and the direction of movement of the car, as well as the signals for opening and closing the doors. *Electrical Engineering B, Drives and Propulsion Systems:* This discipline is concerned with the means of movement of the elevator car. The main components are the electrical motor and the variable speed drives controlling it, as well as the speed feedback devices and position feedback devices. An overview of the electrical energy consumption in elevators is given in Al-Sharif (1996).

Mechanical Engineering: This area involves the mechanical components that comprise the elevator system, such as: the steel ropes, the guide rails, the gearbox, the car frame, the counterweight, the buffers in the pit, and the over speed protection system (Janovsky, 1993).

Structural Issues and Space Planning: A structural support system is required in the building that would support the drive motor and provide guidance to the movement of elevator car, as well as supporting the forces in the elevator shaft pit. Space planning is necessary to ensure that the elevator system and its ancillary component can be installed and safely operated inside the building.

The collective knowledge and expertise in all the disciplines listed above contributes to the successful design and operation of indoor building transportation system. This article will provide a high-level overview of the area of indoor transportation.

General Overview of a Traction Elevator

Elevators are either roped traction elevators or hydraulic elevators. The use of hydraulic elevators is continuously declining, and thus most new elevators are of the roped traction elevators. With reference to the figure shown below, the operation of the roped elevator can be summarized in the following points:

1. An electric motor is used as the hoisting machine. In the majority of cases, the motor is a three-phase squirrel-cage-induction-motor, usually driven by a variable frequency drive system.
2. The electric motor is connected to a sheave, either directly (gearless) or indirectly through a gearbox (geared). Where provided, the gearbox achieves the required reduction in speed and the required increase in torque. A sheave is a pulley that has grooves on its surface. The steel ropes fit inside the grooves on the sheave's surface in order to achieve the required traction (hence the term roped-traction-elevator).
3. The ropes are connected to the elevator car on one side of the sheave and to the counterweight on the other side. The counterweight is basically dead-weights used to balance the car and is made of metal blocks slotted inside a frame. The counterweight is usually equal to the mass of the empty car plus half the passenger rated load. The use of the counterweight allows a small motor to be selected and reduces the energy consumption as it balances all of the dead-load in the system (the mass of the car) as well as half the live-load (the passengers).
4. The elevator car is fitted inside a car frame (informally referred to as a sling). Resilient mountings are fitted between car and the car frame in order to isolate the passengers from vibrations.
5. The travelling path of both the elevator car and the counterweight are guided using guide rails. There are two guide rails for the elevator car and two guide rails of the counterweight. The guide rails only provide lateral guidance but will not prevent or obstruct the vertical movement of the elevator car and the counterweight.
6. Power and signals are connected to the elevator car from the controller using the travelling cable (sometime referred to as the trailing cable).
7. The door fitted to the elevator car is called the car door. This is powered by an electric motor to open it and close it when the car has stopped at one of the landings.
8. The landing doors are not powered but have automatic closers for safety purposes. The closers are either spring operated or weight operated.
9. Once the elevator car stops at a landing and the elevator car doors and the landing doors are correctly aligned, the car door motor opens the elevator car doors, which in turn, engage with the landing door opening mechanism and open the landing doors as well. A similar sequence takes place when the elevator car doors are closed.
10. If for some unexpected reason the elevator car moves away from the landing doors when they are open, the automatic closers will ensure that the landing doors automatically close.
11. The elevator doors and the landing doors have electrical inter-locking safety contacts that prevent movement of the elevator car if any of the doors are not locked.
12. In order to protect against the possibility of the elevator car passing the lowest landing at rated speed (and below the over speed), buffers are installed in the pit of the elevator shaft. The buffers will safety arrest and bring to a standstill the elevator car that is travelling at rated speed. A similar buffer system is also installed under the counterweight.

Figure 1 General Overview of a roped traction elevator Source: From CIBSE Guide D, 2015 with permission).

13. The buffers are generally of two types: Energy accumulation buffers and energy dissipation buffers.
14. In order to protect against the risk of freefall if the ropes are severed, an over speed protection system is installed. The over speed protection system comprises the following:
 - a. A single smaller rope that is connected to the elevator car and causes the rotation of the speed governor wheel that is located in the machine room.
 - b. The speed governor wheel contains a centrifugal mechanism that locks the wheel if the speed of the elevator (as detected by the single small rope) exceeds the over speed value.
 - c. Once the speed governor wheel locks, it pulls on the small rope.
 - d. The small rope activates a mechanical lever on the elevator car.
 - e. The mechanical lever then operates a braking system that is installed on the elevator car, which in turns locks onto the elevator car guide rails

An enlarged view of the roped-traction machine is shown in [Fig. 2](#). The drive motor is usually a squirrel cage induction motor which is mechanically coupled to the gearbox. Sizing of elevator motors can be carried out using the methodology outlined in [Al-Sharif \(1999\)](#). The purpose of the gearbox is to reduce the speed and increase the torque. The output shaft of the gearbox drives a sheave. The sheave is a pulley with grooves on its surface. The traction steel ropes sit in the grooves. The sheave provides traction with

Figure 2 Typical geared traction elevator drive system *Source: From CIBSE Guide D, 2015 with permission).*

the ropes in order to raise and lower the elevator car. A counterweight is connected to the other end of the ropes on the other side. A spring-applied electromagnetically released brake operates on the shaft between the motor and the gearbox. The brake is necessary from a safety point of view in order to ensure the stopping of the elevator car in case of an electrical system failure or when a safety device is operated. In [Fig. 2](#), the bedplate on which the hoisting machine (i.e., the motor, gearbox and its frame) can be seen. Sound isolation pads (usually made of a resilient material such rubber or polyurethane) isolate the hoisting machine from the building structure in order to prevent structural-borne-vibration from being transmitted.

Elevator Traffic Design

The first most important step in sizing elevator traffic systems is assessing the expected passenger demand. Assessing demand depends on usage of the building (e.g., offices, residential, hotel) and on the building population.

Elevator systems have been traditionally sized based on the percentage of the building population arriving in the worst five minutes. This has usually been taken as 15% or 12% of the population arriving during the busiest 5-min period. Modern practices show that this figure is nearer to 10%–12%, due to the prevalence of flexible starting and finishing times ([Stanhope, 2004](#)). More details about assessing demand can be found in [Al-Sharif \(2014\)](#). A typical arrival-departure pattern can be seen in [Fig. 3](#). The curve above the x -axis represents the passenger traffic entering the building which is referred to as incoming traffic or up-peak traffic. The curve below the x -axis represents the traffic departing from the building which is referred to as out-going traffic or down peak traffic. It is the peaks in these two curves that are used as the basis for the design of the system, especially the morning incoming traffic peak.

Once the demand has been estimated, it is then possible to size the main passenger elevator system. This is only the part of the indoor transportation system that caters for the bulk movement of passengers during non-emergency situations. Other aspects of the building transportation needs are addressed later (e.g., goods movement, emergency evacuation, firefighting, kitchen, and waste movement). The number, grouping, and method of control of the elevator system are decided at this stage. Two criteria exist for the selection of the number, speed, capacity, grouping, and method of group control of the elevators: The quality of service and the quantity of service.

The quality of service is best reflected in the interval between the arrivals of the elevators at the main entrance and is called the “interval” and affects quite strongly the passenger waiting time. The quantity of service is best reflected by the number of passengers moved to their destination during a period of 5 min expressed as a percentage of the building population (called handling capacity).

The traffic analysis can then be either carried out using calculation or simulation. Under calculation, the value of the round-trip time (RTT) is calculated. This is then used to find the required number of elevators to achieve the specified value of the interval (usually 30 s), which is representative of the quality of service. This is then followed by another calculation to decide on the required car capacity. For these figures, the handling capacity of the system can be found and matched to the expected passenger arrival rate. More details about the RTT calculations and elevator traffic engineering design can be found in [Al-Sharif \(2014\)](#), [Al-Sharif \(2015\)](#), [Al-Sharif et al. \(2015\)](#).

Simulation can then be carried out to better understand the performance of the system under real life conditions and under the random nature of the passenger arrivals (([Hakonen and Siikonen, 2008](#); [Finschi and State-of-the-art traffic, 2010](#); [Al-Sharif and Al-](#)

Figure 3 Passenger demand for simple traffic survey (page 4-4 CIBSE Guide D, 2015)

Adhem, 2014; Siikonen, 1993; Siikonen, 2000; Siikonen et al., 2000; Peters, 2013)). Simulation can provide more detailed results, such as passenger waiting time, passenger travelling time, and actual car loading. More importantly, simulation can show the effect of the elevator group control system on the performance.

Both calculation and simulation require a number of parameters to be specified such as: Door opening time and closing time; passenger/wheelchair transfer time (affected by factors such as door width, car depth and width, nature of passengers, familiar/unfamiliar); number of passengers boarding the elevator car; acceleration and deceleration times; jerk; inter-floor distances; advance door opening time if applicable. More details about the elevator traffic design for high rise buildings can be found in Wit (2017), To and Yip (2004), Al-Sharif et al. (2017).

Passenger traffic surveys present a powerful tool for verifying existing designs or for understanding the reasons for poor performance (Peters and Evans, 2008). In its simplest form, passenger surveys, as related to elevator traffic engineering, involve the counting of the intensity of passenger arrivals during the busiest 5 minutes during the day. More specifically, human surveyors are often employed to stand in elevator lobbies and count the number of passengers arriving for elevator service in each minute. In cases where there are many elevators in the lobby (e.g., four elevators facing four elevators, or in the case of multiple entrances at different levels), then a number of surveyors are employed. When this is done, it is important to synchronize the time reference in order to ensure consistent data from the different surveyors.

With the advent of modern surveying systems, it is now possible to automate the process and gather much larger amounts of data. Readers who require more details on this topic are referred to chapter 18 of the Elevator Traffic Handbook (Barney and Al-Sharif, 2016).

Space Planning

When planning the installation of elevators in a building, it is necessary to carefully plan the spaces needed. The requirements for the space are closely linked to the capacity of the elevator car, the rated speed of the elevator and the type of drive system.

The elevator rated speed is quoted in units of m s^{-1} and follows preferred values within a Renard series (R-series). The elevator rated capacity is usually cited in units of kg, with the equivalent number of passengers stated as well. The rated capacity in kg also follows preferred values within a R-series. In order to convert from the elevator rated capacity in kg to persons and *vice versa*, it is customary to use a standard passenger mass of either 75 kg or 80 kg.

Internal elevator car width and depth determine whether the elevator car is wide (width larger than depth) or deep (depth larger than width). In the case of passenger elevators, it is preferable to use wide cars, as this speeds up the transfer of passengers into and out of the elevator car and hence contributes to the improvement of the traffic performance of the elevator traffic system. Deep cars are discouraged for passenger elevators but are widely used for goods/service elevators and for bed-lifts in hospitals.

An important standard for the preferred speeds and capacities of elevators and for shaft dimensions is the following ISO standard: “BS ISO 8100-30: 2019 entitled: Lifts for the transport of persons and goods. Part 30: Class I, II, III, and VI lifts installation” (ISO, 2019).

The elevator preferred speeds and loads follow an R10 series (Renard 10). Below are some typical capacities in kg and persons for passenger elevators:

- 630 kg (8 person)
- 800 kg (10 person)
- 1000 kg (13 person)
- 1275 kg (17 person)
- 1600 kg (20 person)
- 2000 kg (26 person)

The numbers shown above in kg follow a Renard 10 (R10) series, and hence are vital in facilitating standardization between different manufacturers, improving competition and allowing planners and architects to provide the required space in the building prior to tendering.

In terms of shaft space planning, the following are the four most critical dimensions in the well space (also referred to as the shaft space):

- The shaft width
- The shaft depth
- The headroom (defined as the vertical distance from the finished floor level (FFL) of the topmost floor to the top of the inside of the shaft)
- The pit depth (defined as the vertical distance from the FFL to the floor at the bottom of the shaft)

The headroom and the pit depth requirement incorporate within them the safety distance necessary to protect the maintenance personnel working on top of the car or in the pit. The main parameters that need to be decided for each elevator are:

1. The shaft width: The shaft width is the clear internal width of the shaft. The width is the dimension that is parallel to the elevator doors direction of opening and closing. It is necessary to add around 150–200 mm for the divider beam between elevators in shaft to allow for supporting structures.
2. The shaft depth: The shaft depth is the clear internal depth of the shaft. The depth is the dimension that is perpendicular to the direction of door opening and closing.
3. The pit depth: The pit depth is the vertical distance between the FFL of the lowest-most floor and the floor of the pit.
4. The headroom: The headroom is the vertical distance between the FFL of the top-most served floor and the underside of the slab at the top of the shaft.
5. The machine room headroom: The headroom inside the machine room is the distance from the FFL on which the motor is placed to the underside of the slab at the roof of the machine room. This ranges from 2000 mm to 4000 mm depending on the size of the motor.

A general overview of the pit is shown in Fig. 4. In this case, the elevator car has two buffers underneath it, and the counterweight has one buffer. At the sides of the pit, the guide rails can also be seen for both the elevator car and the counterweight.

The concept of the “human rectangular block” is an important concept in the protection of personnel working inside the elevator shaft, either in the pit or on top of the car. In the pit, when the car is sitting on the fully compressed buffer(s), the space should be able to accommodate a rectangular block of dimensions $0.5 \times 0.6 \times 1$ m sitting on one of its sides. In a similar way, when the counterweight is sitting on its fully compressed buffer(s), a space should exist above the car that can accommodate a rectangular block of dimensions $0.5 \times 0.6 \times 0.8$ m, sitting on one of its sides.

Figure 4 A general overview of an elevator pit, showing the two elevator car buffers, the counterweight (at the back of the pit) and the guide rails at the sides.

Table 1 Escalator handling capacity for different step widths and different speeds in units of passengers/hour (based on EN115).

Speed (m/s)	Step width (m)		
	0.6	0.8	1
0.5	4500	6750	9000
0.65	5850	8775	11,700
0.75	6750	10,125	13,500

More about the detailed requirements for firefighting elevators can be found in [BSI \(2008\)](#) and Chapter 6 of CIBSE Guide D 2015 ([CIBSE, 2000](#)).

Escalators

Escalators are also an important component of indoor transportation. Escalators have a much higher handling capacity than elevators. They are generally used in cases where a significant flow of passengers is expected over short distances (e.g., one or two floor journeys). This is typical of shopping centers. A table of the handling capacities of escalators in units of passengers per hour is shown in [Table 1](#), based on [EN \(2009\)](#). Real life data of handling capacity on escalators can be found in [Mayo \(1966\)](#).

Most escalators have an angle of incline of 30 degrees. An angle of incline of 35 degrees is allowed by the European norm (EN115-1:2008) if the speed does not exceed 0.5 m/s and the vertical rise is no more than 6 m. An angle of incline of 35 degrees would reduce the space footprint taken up by the escalator. However, there is evidence to suggest that the risk of passenger falls is higher on 35-degree-inclined escalators.

From a mechanical point of view, an escalator is basically an endless chain of consecutive cleated steps that is made to move along an inclined tracking system. A geared motor is installed inside the upper machine space below the upper landing of the escalator. The geared motor is used to provide the movement to the steps. Two endless handrails are also installed and run at the same speed as the step-band. A general overview of an escalator is shown in [Fig. 5](#).

Passenger Conveyors

A moving walkway, moving walk or a passenger conveyor is a device that moves passenger horizontally indoors. It is a very effective and practical means of indoor horizontal transportation, which makes it widely used in airports, railway terminals, and even shopping centers.

In most applications, the moving walkway is horizontal, although it can have an incline of up to 12 degrees (based on the European standard EN115-1:2008). In some cases, it is used to move passengers between different floors. However, even when used in an inclined configuration, steps do not form on the moving walkway and it remains a flat walkway. At an inclination of 12 degrees, this requires extra care by travelling passengers, especially those passengers using shopping trolleys or baggage carts.

The moving walkway usually has rated speeds of 0.75 m/s, although a speed of 0.9 m/s is allowed under certain conditions.

The tread width of the moving walkway can range from 800 mm up to 1400 mm. A width of 1400 mm is ideal as it allows passengers using baggage carts and shopping trolleys to overtake other passengers. The tread way on the moving walkway is either made from metallic pallets (pallets are flat steps similar to those used in escalators) or from belts.

One of the early examples of this device were two inclined moving walkways installed inside a tunnel at Bank Underground station in London. They were opened to the public in September 1960. They are inclined at around 8 degrees to the horizontal and have an approximate inline length of 90 m.

Recent Developments

A number of important developments have taken place in elevator technology in the last 30 years. Although the basic concept of the elevator has not changed since its invention more than 150 years ago, which is basically described as follows:

An electrical motor is used to rotate a sheave (usually through a gearbox that reduces the speed and increases the torque). The sheave (which is a pulley that has a number of grooves on its surface) has steel ropes in the grooves. When enough traction is present between the sheave and the steel ropes, it is possible to raise and lower the elevator car.

The most important of these developments are discussed below.

Advances in Motor and Variable Speed Drive Technologies

Recent advances in motor technology have led to more efficient and more compact motors. The progress of motor technology has progressed through a number of states historically, starting with brushed dc motors, then to geared induction motors driven by variable frequency drives and ending with permanent magnet synchronous motors (PMSM) driven by variable frequency drives.

Figure 5 General Arrangement of a Typical Escalator *Source: courtesy of CIBSE, from CIBSE Guide D, 2015).*

Moreover, the advances in power electronics has revolutionized variable speed drive technology, leading to unprecedented levels of riding comfort for passengers as well as excellent leveling accuracies.

With modern motors and drive technologies and advanced electronic feedback systems, higher speeds are now possible where there are currently elevators in high rise building running at rated speeds of 17 m s^{-1} (17 m/s is equivalent to around 60 km/h), thus reducing the required time to arrive the floor destination in high rise buildings.

Intelligent and Sophisticated Control Systems

There has been a revolution in the processing power, speed and miniaturization of elevator control systems. These systems are employed in the elevator group control systems, allowing better allocation of landing calls to elevator cars in group control, thus reducing waiting times and journey times and avoiding queues. In most cases, these systems have relied on advanced passenger interfaces as well as the use of artificial intelligence tools (such as genetic algorithms, fuzzy logic and neural networks).

Most of the developments in this area have relied on the concept of “passenger grouping” (Christy, 2014). The group control system attempts to group the passengers with common destinations into the same elevator car, in order to reduce the number of stops in a round trip and thus reduce the value of the round trip time and boost the handling capacity.

One such control system that was introduced by the Otis Elevator Company is called channeling (an example is shown in Fig. 6). In this system, each elevator serves a specific set of floors in each journey, when it returns to the main entrance to pick up more

Figure 6 Example of a Channeling system installed in a building in Sydney, Australia.

passengers (Powell, 1992; Fortune, 2002). The floors that it will serve in the next journey are announced using a dynamic electronic display. Thus, passengers will have to board the specific elevator that is serving their destination floor in that journey. Passengers cannot simply board the next elevator car that arrived in the lobby; they must board the elevator that serves their destination floor.

Another group control system that employs passenger grouping is the destination group control. This technology was introduced in the early 1990s by the elevator company Schindler. Details about destination group control systems can be found in Peters (2006), Smith and Peters (2002), Schroeder (1990), Sorsa et al. (2005), Smith and Peters (2004), Lauener (2007), Al-Sharif et al. (2015). It works by asking the passenger to enter his/her destination prior to entering the elevator. The group controller would evaluate the most appropriate elevator car and allocate it to that landing call. It will ask the passenger to wait for that specific allocated elevator in order to board it when it arrives. Once the passenger boards the allocated elevator, his/her car call is already registered, and the elevator car will display it inside as one of the floors at which it will stop. An example of a landing call registration panel is shown in Fig. 7.

Figure 7 Destination Group Control landing call panel.

As mentioned earlier, the effect of passenger grouping in general is that it boosts the handling capacity at the expense of some increase in passenger waiting time.

Optimized Exploitation of Shaft Space in Buildings

A number of innovations have been introduced that aim to optimally exploit the elevator shaft space in buildings by introducing more compact elevator arrangements such as double decker systems and multiple elevators in the same shaft.

The machine room-less elevator was introduced by KONE Elevators in the late 1990s. During the company's search for a linear motor drive elevator, they came across the concept of using a radial (as opposed to an axial) permanent magnet synchronous motor. The advantages of using a permanent magnet synchronous motor, driven by a variable frequency drive system, offered the following advantages:

1. The radial motor (sometimes referred to as a "disk" motor or even informally as the "pancake" motor) was effectively two disks allowed to rotate relative to each other, one with coils fitted to it, and the other with permanent magnets fitted to it. By exciting the adjacent coils with the correct excitation currents, the resultant interaction between the magnetic flux densities of the coils and the permanent magnets allowed the precise control of the speed and torque. This allowed the motor to be run at much lower speeds than conventional induction motors while still providing the required torque.
2. This obviated the need for a gearbox. By eliminating the gearbox, the efficiency of the system improved and valuable space was released, enabling the motor to be fitted inside the elevator shaft, without the need for a machine room.

Since then, all the other manufacturers have introduced their own versions of machine room-less elevators, employing gearless permanent-magnet-synchronous-motors. However, all of them were axial motors rather than radial motors.

Another relevant development was introduced by ThyssenKrupp. It introduced the Twin elevator system that comprises two roped traction elevators sharing the same shaft (Fig. 8). Such a system provides a boost in the handling capacity of the elevator shaft, saving valuable net-lettable area in the building. A number of safety systems provide successive means of protection to prevent the collision of the two elevators cars.

Future Developments

The most important recent development which is expected to transform the landscape of indoor transportation is the new development of the MULTI, a system of elevators electromagnetically propelled vertically and horizontally in a rectangular shaft. Multiple elevator cars can move in the same shaft (hence the name MULTI). The typical arrangement would be a rectangular loop, whereby one vertical shaft is dedicated to the up direction and the other vertical shaft for the down direction. A prototype of this system is shown in Fig. 9.

Figure 8 Two Roped Elevators in the Same Shaft Source: courtesy of ThyssenKrupp Elevators, TKE.

Figure 9 The prototype of a the first MULTI system *Source: courtesy of ThyssenKrupp Elevator.*

Such a system would potentially create savings in the required shaft space for the elevators and allow more flexibility in the movement of passenger within and between buildings. More details about two-dimensional elevator system in buildings can be found in [Gerstenmeyer and Peters \(2014\)](#), [Gerstenmeyer and Peters \(2016\)](#) and [So et al. \(2015\)](#).

A futuristic vision of these system includes elevators moving vertically and horizontally within a “mega-building”, delivering passengers to their exact destination, and even, moving between different buildings. This technology could eventually evolve into a personal “pod” for each passenger that transports him/her to their selected destination in other buildings or even to/from transport terminals such as railway stations and airport terminals. The issues of safety, privacy and security would be some of the challenges that need to be addressed.

Another area that is gaining momentum at the moment is the use of elevator systems in passenger evacuation in buildings. More details about this topic can be found in [CTBUH \(2004\)](#), [Wit \(2010\)](#), [Siikonen and Hakonen \(2002\)](#), [Fortune \(2010\)](#), [Klote \(1993\)](#).

Summary and Conclusions

This chapter has described the main components of indoor transportation, namely elevators, escalators, and moving walkways. Most of the chapter has concentrated on elevators, as they move the majority of passengers inside buildings. Specifically, the article has concentrated on the analysis of the roped traction elevator (the most widely used means of vertical transportation inside buildings), the traffic design process, space planning issues including preferred capacities and speeds, escalators and moving walkways. The chapter has concluded by discussing the most important recent technological developments in this area and the future technological developments. Based on these points, the following is a list of the major areas that require more research:

1. Energy consumption: There will be more focus in the future on the energy consumed in the elevator as well as whole life cycle analysis of its components.
2. There is a need to improve the traffic performance parameters in building transportation, in order to allow more transparency and common terminology.
3. With the advent of rope-less electromagnetically elevators, more research is needed in the area of rope-less propulsion systems and electromagnetically driven elevators in both vertical and horizontal shafts.
4. One of the most important future developments in indoor transportation is the integration of building transportation with intra-building transportation and urban transportation leading to truly integrated transportation systems.
5. There is currently significant demand to include elevator systems in the process of emergency evacuation of buildings. Research in this area is needed on two fronts: evacuation control systems as well as hardware components.

Biographical Notes

Lutfi Al-Sharif is currently Dean of Engineering and Professor of Electrical Engineering at Al-Hussein Technical University in Amman/Jordan and jointly Professor of Building Transportation Systems at the Department of Mechatronics Engineering, The University of Jordan. He received his Ph.D. in elevator traffic analysis in 1992, from the University of Manchester, U.K. He worked for 10 years for London Underground, London, United Kingdom in the area of elevators and escalators.

In 2002, he formed Al-Sharif VTC Ltd, a vertical transportation consultancy based in London, United Kingdom. He has over 30 papers published in peer reviewed journals the area of vertical transportation systems and is co-inventor of four patents and co-author of the 2nd edition of the Elevator Traffic Handbook.

He is also a visiting professor at the University of Northampton (UK), member of the scientific committee of the annual Symposium on Lift and Escalator Technologies and a member of the editorial board of the journal Transportation Systems in Buildings.

He is a passionate believer in making higher education simple and accessible for engineering students and has a YouTube channel on engineering that has more than 55,000 subscribers and around 8.5 million views. He has also been working as a member of the METHODS Erasmus+ Project that aims to improve teaching methods in higher education in Jordan and Palestine. He is also the author of the Mechatronics Engineering Module on Saylor.org.¶

As mentioned in the section on elevator traffic design, simulation is one of the main tools currently used in. Interested readers are also referred to the general use of simulation in transportation in the following two sections: 10186: Simulators and 10638: Modeling and Simulation for Transport Planning.

Surveys are widely used in indoor transportation to verify new installations and to plan for the upgrade of existing installation. More can be found about surveys in the section in the chapter entitled: 10387: Travel Surveys.

This section has been concerned with indoor transportation. For more on passenger outdoors transportation, refer to the chapter in this publication entitled: 10495: Cable Transport.

In indoor transportation, elevators are the means of transport that can be used by mobility impaired passengers. For more information on disability planning in transportation systems in general, readers are referred to the chapter in this publication: 10774: Disability in Transport Planning.

Introduction: Bicycle as a Transportation Option

Bicycles, or simply-bikes, are single-track (i.e., with two wheels) pedal-driven vehicles, and are used across the world for both transportation and recreational purposes. As a mode of transportation, bicycles are inexpensive to purchase and operate, take little road space and have zero emissions. Bicycling (or just “cycling” or “biking”) also provides an opportunity for endurance-type physical activity when used frequently for transportation. For these reasons, advocates, professionals, and some policy makers have highlighted the bicycle as an environmentally sustainable and healthy alternative to automobiles as a transportation choice, and a potential solution to many of the problems posed by the current automobile-dominant transportation systems. Bicycles are also seen as an important component of urban transportations system to ensure “basic mobility”, in other words, to provide basic access to destinations by large population groups regardless of their socioeconomic conditions.

Many of us learned how to bicycle as children and across much of the world, bicycles are popularly used by children and youth to explore their neighborhoods and to be independently mobile. In some societies, particularly in parts of Asia and Europe, bicycles are also seen as an important mode of transportation for the entire population including adults for going to work, school, shopping, and other destinations (e.g., accessing transit stations). In other societies, including much of North America, bicycles are still largely seen as a toy for children, as an exercise equipment or as an undesirable transportation option used mostly by low income people. While these perceptions are changing, they remain a key barrier to wider adoption of bicycles as a transportation mode for working adults, as well as to the development of cycling related policy and infrastructure. In this entry, we focus on bicycles for their potential role as a transportation mode.

For the most part, cycling is a human powered transportation option, although electrically powered bicycles, called e-bikes, are becoming more common. Thus, bicycles are considered most appropriate for short- to medium-distance trips, with North American transportation policies often considering 2–5 km as a typical bikable distance. This bears out in practice. For example, 74% of all bicycle trips in the Toronto Region (the Greater Toronto and Hamilton Area- GTHA) in Canada in 2011 were less than 5 km in length. In some European countries, longer distance bicycle trips are not uncommon and have gained policy attention particularly in the last decade. Countries including the Netherlands, Germany and England have invested in what is called “bicycle highways” to enable longer distance (10–15 km) bicycle trips for transportation purposes.

Pucher and Buehler’s (2012) international comparison of cycling rates further confirms large national differences in bicycle use. While some European countries reported very high-cycling rates, including the Netherlands (26% in 2008), Denmark (18%), and Germany (10%), the mode share of bicycle for daily trips remained very low in other parts of the western world, including 2% in the United Kingdom (UK) (2008), and 1% in the United States (US) (2009). In Canada, 1.5% of population commuted via bicycles in 2016. However, the use of a bicycle is on the rise across these countries compared to even two decades ago. For example, Le et al. (2019) examined bicycle counts at 1319 locations in 13 US metropolitan areas, between 2004 and 2016. Their analysis indicates that cycling volume has increased between 2% and 6% per year at these count locations, controlling for other variations.

The chapter is organized as follows. The next section discusses the social-political history of the bicycle, including national differences in cycling adoption, particularly in Europe and North America. The following section briefly summarizes factors that influence cycling rates as explored in the existing literature, including demographic factors, built environment conditions, and personal attitudes. The paper then turns to the role of bicycle infrastructure development and policy in promoting cycling, and finally concludes by discussing the trajectory of cycling as an increasingly important mode of urban transportation.

A Social-Political History of Bicycles

The early versions of the modern bicycle, featuring two equal sized wheels and a chain-drive, was developed in the late 1800s. These early bicycles were a symbol of the modernization of transportation and were a faster and more practical alternative to horses, which

were the dominant mode of personal transportation at that time (Oosterhuis, 2016). While this new form of mobility was introduced to postal services, the police, fire departments and the army, the general public overwhelmingly adopted bicycles for recreation and sport rather than daily transportation.

Some scholars also suggest that bicycles have played an important role in women's rights movements across the western world (Bopp et al., 2018), when woman had little presence in public life. Gendered expectations for woman included restricted mobilities, with the majority of women in the late 1800s walking to their destinations (primarily relating to household shopping) or using short trolley trips. In this context, bicycles offered an opportunity for longer, more independent travel, and the popularity of bicycles among women grew rapidly in this period. However, female cyclists were criticized for their presence outside of the domestic sphere, and for what was seen as their "liberated attitude" and inappropriate attire (Bopp et al., 2018; Oosterhuis, 2016). As a result, many women cyclists would ride along with men to avoid the "male gaze" and to avoid being painted as symbols of militant feminism (Oosterhuis, 2016), and the overall proportion of women among cyclists was low. Even to this date, gender equity in cycling has yet to be established in many societies. While in some parts of Europe including the Netherlands, Denmark, Germany, and Sweden, there is no significant gendered difference in cycling rates, less than a third of all cyclists in North America are women (Garrard et al. 2012).

Early advocates for bicycle use and better road infrastructure to support cycling in the late 1800s were often wealthy, politically influential people. Before massive road construction to accommodate motor-vehicles, their efforts to establish the right to free mobility on public roads for bicycles was instrumental in the institutionalization of the development of transportation infrastructure as an active government responsibility (Bopp et al., 2018). However, when mass production and lower prices made bicycles more accessible to a larger population, bicycle use began to lose support from elites. Then, in the 20th century, motorized personal vehicles (i.e., cars) quickly came to be recognized as the *avant garde* mode of transportation in many western societies including the US, Canada, England and Australia (Oosterhuis, 2016). In this period, Transportation Engineering and Urban Planning were emerging professions that recognized automobiles as the mobility option for the future and sought to rebuild cities to accommodate motorized traffic. With the exception of some short-lived periods of popularity since the 1940s, the bicycle has continued to fight for road space against automobiles (Wilson and Mitra, 2020).

Some western societies outside the English-speaking world, however, have experienced different trajectories of social and political support for bicycles, and the bicycle has remained much more central to their transportation cultures. In the Netherlands and Denmark, for example, bicycle had already become a national symbol by the 1920s (Oosterhuis, 2016). In the Netherlands, civic organizations emphasized bicycles in terms of "Dutch qualities and civil virtues" and the use of bicycles as a transportation mode was actively promoted. In contrast to the English-speaking world, when bicycles become more accessible to a wider population, they were seen as a "democratic" mode of transportation. These cultures, too, promoted automobile ownership and use after World War II, and there were no significant post-war policy focusing on bicycles until the 1970s oil-shocks. However, bicycles always enjoyed more support and use from all levels of the society. This continues to be the fact to this day, with bicycles seen as an integral element of their urban everyday life.

In contrast, countries such as France, Belgium and Italy embraced cycling as a serious sport, which resulted in the development of world-famous racing/ touring events including the *Tour de France* and *Giro d'Italia*. The commercialization of professional cycling created wide popularity of this sport among both rich and the poor, and the cycling culture in these countries continue to be strongly associated with cycling-related sports.

Still, across Europe today, promoting cycling as a transportation mode and developing extensive systems of bicycle infrastructure is seen as key element to urban sustainability. Some Latin American cities, too, are building extensive cycling systems. Bogota, Columbia is considered a leader in investing heavily in bicycle infrastructure starting in the 1990s to promote bicycle uses as a low-cost transportation mode accessible to the majority of the population. More recently, cycling has received much serious attention as a transportation mode in some North American cities, with New York City, Portland (Oregon), Montreal, Vancouver, and other cities seen as being leaders with accelerated infrastructure investment since the 2000s.

Factors that Influence Cycling

Scholarly literature on cycling behavior is relatively new and smaller compared to the literatures on driving and public transportation use. However, over the past two decades, this literature has grown substantially, and more extensive summaries of current research on cycling behavior can be found elsewhere (e.g., Bopp et al., 2018; Pucher and Buehler, 2012).

Sociodemographic factors such as gender, income, age, and automobile ownership may influence cycling, but the evidence remains mixed. Ironically, while many people view cycling as a transportation option for the poor, some researchers have found that higher income individuals are more likely to bicycle than lower income individuals, and also that cycling is more common among Caucasian sub-population compared to people of color. In addition, younger people tend to favor bicycles more than the older population.

Evidence on gendered differences in cycling is unclear. North American research has consistently reported lower cycling rates among women. For example in the GTHA, Canada, only 29% of all cyclists were women. In the United States, 24% of all cycling trips were taken by women. Further, between 2000 and 2010, the number of female cyclists in the United States actually went down by 13% (www.bicycle-guider.com). But such gender difference is almost non-existent in communities and countries with stronger cycling culture and relatively higher cycling rates. In some inner urban neighborhoods in Toronto, Canada, for example, where more

than 10% adults commute to work/school by bicycle, the cycling rates are similar for both men and women. While the causal relationship is unclear, advocates often argue that encouraging women to bicycle is an important way to promote and increase bicycling rates at the population level. Chapter 10637 of this volume offers a more broader discussion of gendered mobility.

In terms of the urban built environments, researchers have provided evidence of correlations between cycling rates and measures of population/ development density, land use mix and traffic and personal safety (Bopp et al., 2018). Communities with higher densities have higher rates of walking/cycling than low-density neighborhoods. However, other researchers point to the roles of land use mix and street design characteristics as being key factors beyond population density. As discussed in the next section, cycling advocates and professionals have always emphasized bicycle infrastructure as a critical factor in promoting the bicycle and advancing cycling at a population level.

Previous studies have also emphasized the importance of travel distance on the likelihood of cycling. For example, Dill & Carr (2003) reported that trip distance was the most frequently cited reason for avoiding cycling as a means to commute to work, although this conclusion may be particularly relevant to North America. In Europe, the use of bicycles for long distance commutes and as a means to complete the first/last mile trips (e.g., trip to train station) is more common.

In addition, the decision to bicycle is clearly influenced by personal attitudes, social norms, and self-efficacy or confidence, compared to some other major modes of transportation such as driving or taking transit where it is believed that the generalized travel cost is the key determinant of travel mode choice (see Chapter 10513 for a detailed discussion of the generalized cost of travel). Although limited, existing research has consistently reported that those who enjoy cycling are more likely to commute by bicycle. Positive attitudes toward cycling and being environmental conscious, also may encourage cycling for transportation (Bopp et al., 2018). Chapter 10675 of this volume provides a detailed discussion of the behavioral psychology of cyclists. Because cycling is generally considered to be a less safe mode of transportation compared driving or taking transit, confidence in cycling has been identified as a key indicator of whether and how frequently an individual bicycles for transportation. An emerging literature on cyclist typology suggests that only very confident cyclists are willing to bicycle in traffic with no or little dedicated infrastructure (Dill and McNeil, 2013). Most of the population who are interested in bicycling, however, report they desire high-quality dedicated infrastructure before they would consider regularly cycling for transportation due to safety-concerns

Bicycle Infrastructure and Active Transportation Planning

Chapter 10116 of this volume discussed bicycle infrastructure. Bicycle infrastructure is arguably a key enabling factor to improve cycling rate. Very high cycling rates in some European countries, such as the Netherlands, is often credited to the existence of expansive and well-designed bike-path network and other bicycle-related infrastructure and facilities. Previous research has consistently reported an association between the availability of bicycle parking and commuting by bicycle (Bopp et al., 2018). While bicycle parking and storage is an important component of many active transportation plans, most policy and plans focus on providing painted bicycle lanes, on-street separated cycle tracks or off-street bicycle paths/trails. For example, between 2014 and 2016, we examined nine Complete Street projects and 13 active transportation improvement projects in the Greater Golden Horseshoe Region of Canada (i.e., the large urban region around the City of Toronto). Every project included an improvement to bicycle infrastructure.

The association between higher rates of cycling for commute purposes and the presence of bicycle infrastructure is consistently shown in the literature. For example in US cities, higher amounts of bicycle infrastructure has been shown to be related to higher rates of bicycle commuting regardless of socioeconomic factors, land use, cycling safety, transit supply, gasoline price, and climate (Buehler and Pucher, 2012). Bicycle infrastructure improves accessibility between locations and creates a safer bicycling environment, thereby may encourage more cycling by both current and “new” cyclists. However, it is difficult to isolate the impacts of a particular infrastructure investment, such as one new bicycle lane on a street segment especially as bicycle infrastructure is easier to implement (and expand) in locations where there is stronger community support and political leadership (Wilson and Mitra, 2020). Thus, the relationship between infrastructure supply and demand may be reciprocal, with cycling demand and a culture contributing to the development of a robust bicycle infrastructure.

In this context, an emerging body of research has attempted to systematically examine bicycle infrastructure, but with only mixed results. Several studies have surveyed cyclists who were using a newly built cycling facility (e.g., cycle track, multi-use trail) in the US and Canada, and found that at least a quarter of current users would have chosen another mode for a similar trip in the absence of a bicycle infrastructure (Mitra et al., 2016; Rowangould & Tayarani, 2016). In Australia and the UK, studies using case control and/or longitudinal data did not find a statistically significant mode substitution effect (e.g., driving to cycling) as a result of a new bicycle infrastructure (Rissel et al., 2015; Song et al., 2017). Instead, an increase in bicycle counts on streets with bicycle infrastructure were attributed to a potential route substitution, where those who were already cycling on other streets were using the newer and potentially safer infrastructure.

More recently, our study of 17 neighborhoods in Toronto, Canada and the surrounding urban region (11 with a bicycle infrastructure; six without) produced more in-depth insights. After two-to-three years of construction, those living near a new bicycle infrastructure were more likely to commute by bicycle regularly (at least once a week) compared to those living in neighborhoods without a cycling facility (Odds Ratio = 1.5), but this difference was not statistically significant. Instead, those who were already cycling regularly before 2017, were cycling more frequently in 2019 when they lived near a newly built bicycle infrastructure, compared to those regular cyclists who lived in neighborhoods with no new bicycle infrastructure (Odds Ratio = 2.85). The results are not entirely unexpected. In North America in particular, bicycle lane/ tracks are often planned and

built in isolation without proper connectivity to the broader network of bicycle infrastructure. Creating better connected networks of on-street bicycle infrastructure would produce meaningful improvements to accessibility and cyclist safety and may have a more measurable impact. Besides, creating safer transportation conditions for existing cyclists is an important policy rationale.

Perhaps the biggest limitations of advancing bicycle infrastructure are public opposition and as a result, the lack of political support toward on street bicycle lanes and cycle tracks (Wilson and Mitra, 2020; Wild et al., 2018). Building off-street bike trails that do not compete for roadway space is more popular and is less politically charged than on-street facilities, but are still challenging to finance. Wilson and Mitra (2020) explain this opposition by situating bicycle planning within a broader cultural context where automobiles are not just seen as a means for transportation, but are considered an extension of the private sphere and something that protects families from “dangers” of the outside environment. Not surprisingly, maintaining the dominance of automobiles on roads is a key popular and political priority.

Even in cities with relatively high cycling rates, such as Copenhagen, Denmark; Seville, Spain; New York, US and Vancouver, Canada, imposing limits on cars, or taking away a driving lane from an urban road is a difficult undertaking (Wilson and Mitra, 2020). Building off-street facilities also requires political support and substantial funding. This is seen, for example, with the recent European experience of building long-distance “bicycle highways.” In the Netherlands, with its long history of public support for cycling, the central government supported communities in building 30+ of these facilities. In comparison, in Germany, the central government left financing in the hands of regional and municipal governments, which significantly slowed down the implementation due to lack of resources. Competition for road space and funding between motor vehicles and bicycles remains and may continue to be a major policy and professional challenge in improving cycling infrastructure.

Still, the bicycle as a mode of transportation is becoming more popular across the western world, influencing policy and active transportation plans that are creating new opportunities to promote cycling and create bicycle infrastructure. The European Commission, for example, advocates that Sustainable Urban Mobility Plans (SUMP) to be developed by all towns and cities, promoting modes with low-environmental impacts such as walking and cycling (Consult, 2019). Research networks such as Physical Activity Through Sustainable Transport Approaches (PASTA; www.pastaproject.eu) have also been established that aim to further demonstrate the health benefits of cycling. In the US, over 1400 agencies at all levels of government have adopted Complete Streets Policies that often focus on improving cycling safety, and 31 States now recognize a bicycle as a vehicle, allowing laws and regulations focusing on the safety of the cyclists (Bopp et al., 2018). In 2010, the US Department of Transportation called for the collection of more active transportation data, resulting in a range of tools and approaches to measure bicycling in US communities (Bopp et al., 2018). Since 2005, Federal Government commitment to the Safe Routes to School (SRTS) programs has resulted in the construction of significant bicycle infrastructure. In Canada, Montreal, Quebec has long been a leader in promoting both urban and long distance cycling, but cycling planning and infrastructure development is also becoming institutionalized in the rest of the country, with provincial funding being provided for local projects, and all major cities actively developing new facilities.

Conclusion: Cycling to the Future?

Bicycles predate automobiles as a form of modern, urban transportation mode. In much of the western world, this role was displaced by motor-vehicles, as 20th century cities were increasingly planned for and became dominated by automotive travel, particularly so in North America. Bicycles not only became marginalized on increasingly hostile roadways, but, outside of childhood and recreational contexts, were also associated with marginalized populations. Bicycles were perceived as a transportation option for people who did not have “better” options.

More recently, however, northern European cities such as Amsterdam, the Netherlands and Copenhagen, Denmark have become models for what cycling can be, with some 35% or more of work trips made by bicycle. This achievement required decades of activism, government policy, and infrastructure investment to realize, but also demonstrate what could be possible in other cities. Indeed, almost all European cities have now been influenced by these lessons and see the bicycle as a key to improving urban sustainability, public health and social equity. Even large cities, such as London and Paris, are reallocating road space away from automobiles, and dedicating it to cycling facilities. While political and financial support can be hard fought, bicycles are, once again, seen as a modern and progressive form of transportation, suitable for adults as well as children, for women as well as men and, indeed, as a low-cost, zero-carbon, healthy form of transportation for all classes of society.

Cycling rates are much lower in North America, but cycling and bicycle infrastructure are also increasing in the US and Canadian cities. Whereas cycling is still seen as being low status by some parts of the population, research shows that cycling is actually positively associated with income and it is, in fact, in desirable, gentrifying central-city neighborhoods where cycling rates are the highest. Not only are these built environments more supportive for cycling than in neighborhoods developed after World War II, but their residents with many transportation options are choosing cycling as a desirable mode of travel that is representative of modern, urban lifestyle. Indeed, some marginalized neighborhoods have resisted the building of new bicycle lanes, seeing them as a harbinger of gentrification. Still, Portland, Oregon, and New York City have become their own models for bicycle planning. In the last decades, for example, New York has added over 2000 kilometers of bicycle lanes and New York’s expertise has been incorporated into guidelines published by the National Association of City Transportation Officials (NACTO, 2012), itself having been established only 25 years ago. That expertise is now being exported across North American, and often to other cities around the world.

There are major opportunities and challenges for continuing this trajectory. In particular, the planning response to COVID-19 pandemic has accelerated existing cycling plans and new cycling infrastructure has been rapidly created in scores of cities. People avoiding public transit due to health concerns has led to dramatic increases in cycling rates, but others may be turning to more auto use, potentially creating increased competition for roadway space. It is not yet clear where new bicycle infrastructure (that are being built as part of the post-COVID19 recovery strategies) will be made permanent, and where it will be pared back, nor what the “new normal” in travel patterns may be as public health concerns from COVID-19 become less pronounced. This will clearly vary geographically. In North America, for example, the built environment conditions outside of city cores is often difficult for cycling, with large, multi-lane arterial streets designed for cars, low densities, and long distances between destinations, all features that research suggests will limit bicycle use. While there is more space in these areas and some suburban municipalities are building off-street paths, reallocating space or capital funding away from automobiles faces political opposition and as a result, cycling facilities are often fragmented, rarely forming continuous networks of bicycle infrastructure. Thus, it is clear that tensions will remain between environments planned and designed for automobiles, and those that accommodate safe and convenient cycling.

It is also clear, however, that cycling, even in the suburban contexts, was on the rise both in areas with and without cycling facilities even before COVID-19 pandemic. This will continue to create additional demand for infrastructure and continue to build a cycling culture in a virtuous circle. In a world where environmental sustainability, health, and social equity are seen as key issues, bicycles are being seen as contributing to solutions. The emergence of new micro-mobility options such as electrically powered bicycles (e-bikes) and electric pedal scooters (e-scooters) and their recent popularity are something to be acknowledged in this context. In the past few years, e-bikes and e-scooters have become common features in hundreds of cities across Asia, Europe and North America, primarily in the form of pay-per-use (e.g., bike-share, scooter-share) services. Whether or not these new mobility options will impact the rates of cycling in the coming decade remains to be seen. But the future of cities increasingly looks like one in which bicycles will play a central role.

Introduction: What is Urban Air Mobility and On-Demand Aviation?

Urban Air Mobility (UAM) (also known as advanced air mobility) is an emerging concept that envisions a safe, sustainable, affordable, and accessible air transportation system for emergency management, cargo delivery, and passenger mobility within or traversing a metropolitan area. UAM is part of a broader ecosystem of on-demand mobility where consumers can access mobility and goods delivery services on demand by dispatching or using urban aviation services, courier services, shared automated vehicles, shared mobility, public transportation, and other innovative and emerging transportation technologies.

Across the globe, a number of converging innovations, such as advancements (e.g., vertical lift, electrification, and automation) and the growth of app-based services are contributing to the concept of on-demand aviation, including UAM and rural air mobility (for less urbanized areas). Although the concept of UAM is not new - several helicopter services began providing early UAM services in Los Angeles, New York City, San Francisco, and other metropolitan areas in the 1950s, 1960s, and 1970s. In recent years, on-demand aviation services similar to transportation network companies (TNCs) dispatched through a smartphone app have entered the marketplace (Cohen et al., 2020). For example, in the United States, BLADE provides helicopter services booked through a smartphone app in numerous cities (e.g., Los Angeles, Miami, New York City, and San Francisco). BLADE employs third-party operators that own, manage, and maintain their aircraft under federal regulations that govern intrastate air taxis and commuter services (BLADE, 2019). Similar helicopter services, such as Airbus' Voom are operational in Mexico City, Sao Paulo, and the San Francisco Bay Area. Travelers can use Voom to request on-demand flights from partner air taxi companies. Trips can be booked anytime between one hour to 90 days in advance through the Voom app or website (Voom, 2020).

In recent years, several companies are developing and testing enabling elements of a contemporary UAM concept including prototypes of vertical take-off and landing (VTOL) capable aircraft, operational concepts, and market studies to understand potential business models. Original equipment manufacturers are developing a variety of piloted, remote piloted, partially automated, and fully autonomous aircraft for a variety of applications. Common terms and definitions are summarized in Table 1.

In the United States, The National Aeronautics and Space Administration's (NASA) Advanced Air Mobility (AAM) National Campaign aims to improve UAM safety and accelerate scalability through demonstrations beginning in 2020. In addition to public sector research, a number of TNCs, such as Uber and Grab, are also working to develop their own UAM delivery and passenger services in partnership with electric VTOL (eVTOL) aircraft and small unmanned aerial systems (also known as sUAS and drone) manufacturers. A number of planned delivery services (for consumer goods and medical supplies) using sUAS/drones are being explored. Planned passenger services using eVTOL include Dallas, Los Angeles, Melbourne, and Singapore (Etherington, 2020; Hawkins, 2017).

Table 1 Common terms and definitions

Small Unmanned Aircraft	Aircraft that weigh less than 55 pounds (or 25 kg) on take-off, including everything that is on board or otherwise attached.
Small Unmanned Aircraft System (sUAS)	Small unmanned aircraft and its associated elements (including communication links and the components that control the small unmanned aircraft) that are required for the safe and efficient operation of the small unmanned aircraft in the national airspace system.
Vertical Take-off and Land (VTOL)	An aircraft that can take off, hover, and land vertically.
Rural Air Mobility	Envisions a safe, sustainable, affordable, and accessible air transportation system for passenger mobility, goods delivery, and emergency services within or traversing rural and exurban areas. Rural air mobility could include travel between a rural and urban area.
Urban Air Mobility (UAM)	Envisions a safe, sustainable, affordable, and accessible air transportation system for passenger mobility, goods delivery, and emergency services within or traversing metropolitan areas.
Unmanned Aircraft Systems Traffic Management (UTM)	A traffic management system that provides airspace integration requirements, enabling safe low-altitude operations. UTM provides services such as: airspace design, corridors, dynamic geofencing, weather avoidance, and route planning.

While UAM may be enabled by the convergence of several factors, several challenges such as: community acceptance, safety, social equity, issues around planning and implementation, airspace, and operations, could create barriers to mainstreaming. While numerous societal concerns have been raised about these approaches (e.g., privacy, safety, security, social equity), on-demand aviation has the potential to offer additional options for emergency services, goods delivery, and passenger mobility in urban and rural areas using small piloted, remote piloted, and autonomous aircraft (Shaheen et al., 2020).

This chapter is organized into four sections. The first section discusses potential barriers and challenges to implementation. Next, potential use cases of UAM are discussed. In the third section, the role of research, regulation, and demonstrations in developing policies and programs to guide the use of on-demand aviation are discussed. The chapter concludes with a discussion of how COVID-19 is presenting opportunities to demonstrate medical, emergency response, and sanitation use cases to build community acceptance of this novel aviation concept.

Potential Barriers and Challenges

Renewed interest in on-demand aviation coupled with innovative and emerging technologies has increased awareness about potential UAM societal concerns. In spite of an array of potential use cases and applications for on-demand aviation, UAM could face notable safety, financial, and community acceptance challenges, among others. Potential challenges to UAM deployment and adoption are summarized in Table 2.

Potential UAM Use Cases

UAM may serve a variety of use cases, such as emergency response, goods delivery, and passenger mobility and has the potential to:

- Support emergency management missions including: air ambulance, emergency supply delivery, organ transport, and search and rescue operations;
- Expand access to goods delivery, particularly in remote locations; and
- Enable additional mobility and delivery options.

A few potential UAM market segments and service models are described in Table 3.

There is a lack of research and understanding about the: (1) environmental, (2) travel behavior, (3) lifecycle, and (4) surface transportation network effects of implementing UAM. Research, pilot projects, and public policies could help to address many UAM concerns.

The Role of Research, Pilot Demonstrations, and Regulation

Due to the exploratory nature of UAM, more research is needed to better understand the potential impacts of UAM. Numerous efforts are underway across the globe to explore potential UAM opportunities and challenges to guide the use of on-demand aviation.

A few research gaps include:

- How will travelers' access vertiports, both from their origin and to their destination?
- How will UAM impact modal shift? Will UAM remove enough vehicles from the surface transportation network to make a noticeable impact on congestion? Could UAM induce travel demand due to reduced travel times or encourage more people to drive (due to reduced congestion from travelers switching to UAM)?
- How many gas-powered vehicles could UAM remove from the road?
- What are the lifecycle emission impacts associated with UAM compared to other transportation modes?
- What are the broad land use and societal impacts of UAM on communities?

Table 2 Potential barriers and challenges to UAM deployment and adoption

Potential barriers and challenges	Description	Use case		
		Emergency Management and Response	Goods	Delivery
Passenger Mobility				
Affordability and Social Equity	With respect to passenger mobility, current UAM passenger services are premium offerings that have, in recent years, typically averaged \$149–300 US per seat using traditional helicopters. At present, there are concerns that UAM may not be an affordable transportation option by lower- and middle-income households, and UAM may be used by upper income households to avoid congestion. Electrification and automation of UAM could reduce costs; however, uncertainty exists about whether UAM can obtain mass-market affordability. Additionally, it is important for UAM to be accessible for people with disabilities and other users with special needs. Similar concerns about affordability could also be associated with some emergency response use cases, such as medical transport (e.g., people without any or sufficient levels of medical insurance coverage may not be able to afford aeromedical use cases and/or be left with unaffordable medical transportation bills after using the service).	X		X
Aesthetics and Visual Pollution	An overcrowding of low-altitude aircraft in urbanized areas could create unwanted visual disturbances, particularly for non-essential use cases, such as mobility that could be accomplished with surface modes and drone delivery for retail packages.		X	X
Noise Pollution	Noise pollution is a potential problem that could arise with multiple low-altitude aircraft in urban areas. In the future, the use of conventional helicopters for early UAM passenger mobility service could increase community concerns about noise and limit adoption, particularly for non-essential use cases, such as passenger mobility and retail goods delivery. UAM may need to meet a stricter noise standard due to multiple aircraft, rotorcraft, and drones operating a low altitude over populated urban areas.		X	X
Increased Aircraft Activity Over Residential Areas	Residential communities may be concerned with low-altitude aircraft flying over homes and yards due to safety, privacy, noise, aesthetic, and other concerns. For example, residential communities could be particularly concerned about during the evenings, late night, and weekends due to concerns about privacy and noise disturbances at times when most residents are sleeping.		X	X
Electrification and Range Anxiety	While electrification has the potential to offer reduced emissions, scaled UAM operations could have an impact on the electric grid. Additionally, there could be performance and safety concerns associated with battery weight and energy storage in different climates, as well as consumer concerns associated with range anxiety. For emergency response use cases employing larger aircraft (e.g., air ambulance), electrification and range limitations could be notable barriers to adoption. Emergency response use cases with electric aircraft create notable operational challenges that must be considered, such as increased downtime due to charging and reduced mission flexibility due to limited range (requiring an aircraft to return to its base for recharging). This can result in greater downtime for electric aircraft compared to hybrid and gas-powered alternatives, including existing air ambulance services using helicopters. Technological innovations, such as improved battery capacity, reduced charging times, and battery swapping could help overcome some of these limitations.	X	X	X
Remotely Piloted and Autonomous Operations	There are a variety of technical and operational challenges that must be overcome before UAM can be deployed in urban areas at scale. In particular, there could be community concerns associated with remotely piloted and autonomous aircraft (both from the perspective of users and non-users). Machine learning and other algorithms used for automation are non-deterministic, which means that even for the same input, the algorithm may exhibit different behaviors on different runs. This could present challenges for certifying that these systems are safe for autonomous flight. Finally, there are a number of technical and security concerns (i.e., unmanned traffic management and cybersecurity) that will need to be addressed to accommodate remotely piloted and autonomous operations.	X	X	X
Airspace and Unmanned Traffic Management (UTM)	Integrating innovative and emerging aviation technologies into an existing, antiquated, and analog system of air traffic management can pose notable challenges for UAM, particularly as the number of new users of low-altitude airspace is projected to increase. A core challenge is enabling an automated air traffic management system that can handle increasing flight activity into a single ecosystem that accommodates an array of airspace users and communication methods. Designing a system that leverages the latest innovations, while ensuring cybersecurity and backward compatibility with existing systems, could be key.	X	X	X
Safety and Certification		X	X	X

Business Model and Financial Sustainability	Concerns about safety, particularly with new aircraft types coupled with scaled operations over highly urbanized areas could present challenges for UAM. Additionally, most aviation authorities lack defined certification categories for UAM aircraft that in many cases may contain novel features and combinations of features that are not typically found in other aircraft (distributed electric propulsion/tilt-wing propulsion, VTOL, autonomy hardware and software, and others). For goods delivery use cases, in particular, potential interactions between untrained individuals and drones could present significant safety challenges.			
	Each category of use cases presents their own business model and financial challenges. For the emergency response use case, a NASA market study examining the viability of air ambulance vehicles found that electric VTOL aircraft, in the best case scenarios, could only yield nominal cost savings over helicopters due to the high fixed costs of flight crews and medical personnel, limited range, and increased operational complexities. Drone delivery presents related challenges. A ratio of one drone to one package is likely an inefficient method of delivering a network of packages to a community. While early launches using eVTOL aircraft are expected in the early to mid-2020s, profitable passenger services are not anticipated until the late-2020s and early-2030s, based on exploratory market studies. Table 3 Potential UAM market segments and service models

Market segment	Service models
Emergency Management and Response	<i>Medial Response, Evacuation, and Transport</i>—Providing medical care, evacuating patients from an incident scene, and transporting them to medical facilities <i>Disaster Response</i>—An array of missions that could include warning/evacuation, search and rescue, firefighting, assessing damage, providing immediate assistance, and restoring critical infrastructure <i>Disaster Relief</i>—An array of missions to help provide relief to return a community back to normal following an incident or disaster (e.g., distributing food and supplies)
Goods Delivery	<i>Small Unmanned Aircraft Systems (sUAS)</i>—A small aircraft (and enabling elements such as communication links) that weighs less than 55 pounds on take-off, including everything that is on board or otherwise attached (i.e., a package)
Passenger Mobility	<i>Personal Aircraft</i>—An aircraft that serves an individual or party for a length of time greater than the duration of a single flight <i>Air Pooling</i>—An on-demand service where multiple individual users share an aircraft <i>Air Taxi</i>—An on-demand service for a single user or group of users that reserve an entire aircraft for a flight and determine the flight's origin, destination, and timing <i>Semi-Scheduled Service</i>—A model with semi-flexible scheduling that can be modified to meet a customer's preferences (e.g., a flight scheduled to depart within a 2-h window) <i>Scheduled Service</i>—Offering near on-demand by offering frequent flights along a route with regularly scheduled service

Source: (Reiche et al. 2018; Patterson et al. 2018; McKinsey and Company 2018)

More research is needed to:

- Study the environmental impacts of UAM implementation and policies to support sustainability;
- Understand how to integrate UAM and small UAS (i.e., drones) into the same airspace and traffic management system;
- Research the safety and health impacts of UAM (including personal safety onboard autonomous aircraft, such as crime);
- Identify data needs, including data metrics, data formats, and standards for sharing;
- Model the potential traffic and land use impacts of UAM on the community;
- Identify flight path profiles for innovative aircraft and if traditional helipad approach paths should be adapted or changed;
- Understand public perception of aviation technologies, such as issues associated with electric range anxiety, willingness to fly on autonomous aircraft, etc.;
- Identify best practices for multimodal integration and vertiport design; and
- Study the social equity and economic impacts of UAM on communities (e.g., opportunities for increased employment, reduced ground vehicle traffic, accessibility for UAM by disadvantaged communities and users with special needs) (Fig. 1).

A number of public sector initiatives have begun to explore these unanswered questions and challenges. Key research, demonstration, and regulatory developments from the National Aeronautics and Space Administration (NASA), the US Federal Aviation Administration (FAA), the European Union Aviation Safety Agency (EASA), and the International Civil Aviation Organization (ICAO) are summarized further.

**Figure 1** Understanding and guiding the potential UAM impacts.

Figure 2 Urban air mobility maturity levels. Source: NASA.

NASA's Advanced Air Mobility National Campaign

In the United States, NASA's Aeronautics Research Mission Directorate (ARMD) launched the advanced air mobility working groups in Spring 2020 focused on enabling the UAM ecosystem through collaboration with public, private, and academic stakeholders. NASA has also developed a series of urban air mobility maturity levels intended to overcome vehicle, airspace, and community integration barriers from an initial to mature state (Fig. 2). NASA's *Advanced Air Mobility National Campaign* aims to improve UAM safety and accelerate scalability through integrated demonstrations through a series of ecosystem-wide challenges beginning in 2020. It is envisioned that the AAM National Campaign will support the United States. FAA in developing an approval process for UAM aircraft certification, develop: (1) flight procedure guidelines, (2) evaluate communication, (3) navigation and surveillance requirements, (4) define airspace operations management activities, and (5) characterize vehicle noise levels. The first testing opportunity in the National Campaign will focus on the testing of US developed aircraft and will include airspace operations management services to explore architectures and technologies needed to support future UAM safety and scalability of operations (Garrett-Glaser, 2019).

FAA's Unmanned Aircraft Systems (UAS) Integration Pilot Program (IPP)

In addition to the AAM National Campaign, the FAA's UAS Integration Pilot Program is helping the US Department of Transportation (DOT) develop new rules for unmanned aircraft (e.g., drones) that support more complex low-altitude operations by: (1) identifying ways to balance local and national interests related to drone integration; (2) improving communications with local, state, and tribal jurisdictions; (3) addressing security and privacy risks; and (4) accelerating the approval of operations that currently require special authorizations. Key goals of this initiative include establishing a dialog between local and national interests related to drone integration and providing actionable information to the US DOT on expanded and universal integration of drones into the National Airspace System. The IPP has funded nine lead participants that are evaluating a host of operational concepts including: package delivery, flights over people and beyond the pilot's line of sight, night operations, detect-and-avoid technologies, and the reliability and security of data links between pilot and aircraft (FAA, 2019). While the IPP has started this conversation, the industry still has not perfected the integration of unmanned systems for small unmanned aircraft (aircraft that weigh less than 55 pounds on take-off) nor large UAS into routine operations. Leveraging emerging lessons learned from the IPP, in Summer 2020 the FAA released the UAM Concept of Operations (ConOps) v1.0 which presents an air traffic management vision to support initial UAM operations in urban and suburban environments. The ConOps provides an initial framework for evolving from initial low complexity and low frequency operations to more mature operations with increasing frequency and complexity.

EASA Regulatory Developments

Similar to the FAA, the EASA certifies, regulates, standardizes, investigates, and monitors air transportation for the European Union. In May 2017, EASA published UAS regulations. In January 2019, the European Union, outside of EASA, passed UAS regulations that guide UAS operations and licensing. In Summer 2019, EASA published a special condition for certification of small electric and hybrid VTOL aircraft. The regulation establishes two categories of aircraft: basic and enhanced. Basic aircraft certification standards will be used for personal and rural aircraft. Enhanced aircraft certification standards apply to aircraft used in commercial operations and flight over urban areas. The regulation allows for aircraft with a pilot on board, remotely piloted, or various degrees of autonomy (EASA, 2019). In Summer 2020, EASA released a means of compliance (MOC) publication with draft guidance for manufacturers of

multirotor, lift-plus-thrust, and vectored thrust aircraft configurations. The document is intended to provide manufacturers guidance on how to comply with certification requirements.

ICAO Regulatory Developments

Internationally, ICAO regulates aviation safety, security, efficiency, regularity, and environmental protection for international air travel. In 2011, ICAO published a report that set standards for UAS airworthiness and licensing. However, laws regulating UAS vary by country. In an ICAO executive meeting in July 2019, UAM was presented by the United Arab Emirates as a high-level policy issue that required ICAO's input. ICAO determined that UAM poses a variety of challenges including lack of certification definitions and operational rules, lack of guidance to develop regulatory frameworks, gaps in existing information on unmanned systems, and a need for further research (ICAO, 2019). At present, international regulation on UAM is limited. Organizations including EASA and US-based ASTM International are working on developing airworthiness certifications for UAM and VTOL.

Air traffic management and public policy may need to evolve quickly to safely manage a growing number of new airspace users. Additionally, while many aviation authorities have emphasized national pre-emption of regulatory authority of the airspace, local and regional governments may argue for more local control over when and where urban air taxis fly. While many of these regulatory challenges have yet to be addressed, the policy environment will likely need to adapt quickly to emerging aviation technologies (e.g., electrification and automation) and new users of the airspace, such as UAM and small UAS package delivery.

Conclusion: Leveraging COVID-19 Medical and Sanitation Use Cases to Build Community Awareness

COVID-19 has presented a meaningful moment to demonstrate the potential of UAM and UAS, particularly in providing critical goods delivery and medical response. In May 2020, United Parcel Service began to expand its drone delivery program with CVS Health Corporation to delivery prescription medications to more than 135,000 residents in a Florida retirement community. In Ghana, California-based drone start-up, Zipline, began delivering critical medical supplies and COVID-19 test samples in Accra and Kumasi. In the United Arab Emirates and Indonesia, communities are using drones to spray disinfectant as part of a program to sanitize urban streets. In China, drones have been used to remind people to wear a facemask and to maintain social/physical distancing. These represent a handful of examples of how the COVID-19 pandemic has helped push UAS and UAM from the fringe to a potential strategy for emergency evacuation, response, and delivery of life saving equipment, tests, and medications. Although these examples are relatively limited, COVID-19 could be the moment that helps raise community awareness of this nascent aviation sector. Moving forward research on the potential impacts of UAM, coupled with prudent planning and implementation, are needed to balance commercial interests, technology innovation, and the public good.

Acknowledgment

The authors would like to thank the National Aeronautics and Space Administration and Toyota Motor Company for their generous support of this research.

Biographies

Adam Cohen is a mobility futures researcher at Innovative Mobility Research Group at the Transportation Sustainability Research Center (TSRC) at the University of California, Berkeley. Since joining the group in 2004, his research has focused on innovative mobility strategies, including urban air mobility, vehicle automation, smart cities, last mile delivery, shared mobility, smartphone apps, and other emerging technologies. Adam has published numerous peer-reviewed journal articles and reports on innovative and emerging transportation technologies and the future of mobility. Adam also served three combat tours in support of Operation Enduring Freedom as a rated aviator. Adam's unique multidisciplinary background gives him unique insight into automation, electrification, landside and airside aviation issues, and the potential impacts of innovative and disruptive technologies. Previously, Adam worked for the US Department of Homeland Security (DHS) and the Information Technology and Telecommunications Laboratory (ITTL) at the Georgia Tech Research Institute (GTRI). His academic background is in city and regional planning and international affairs.

Susan Shaheen is a professor in the Department of Civil and Environmental Engineering and a research engineer with the Institute of Transportation Studies at the University of California, Berkeley. She is also Co-Director of the Transportation Sustainability Research Center at UC Berkeley. She was among the first to observe, research, and write about the changing dynamics in shared mobility and the likely scenarios through which automated vehicles could gain prominence. She was the policy and behavioral research program leader at California Partners for Advanced Transit and Highways, a Special Assistant to the Director's Office of the California Department of Transportation, and the first Honda Distinguished Scholar in Transportation at the Institute of Transportation Studies at UC Davis, where she served as the endowed chair until 2012. She has authored 73 journal articles, over 125 reports and proceedings, 18 book chapters, and co-edited two books. She has a PhD from UC Davis and an MS from the University of Rochester.

Introduction

Transport modes enable mobility which drives social and economic developments and allows people to access services, jobs, education, and the interactions that help create fulfilled lives. However, the transport sector, as one of the top consumers of fossil fuels, is a major contributor to air pollution and generates a variety of emissions which impact the climate. This chapter presents how transport modes relate to sustainability, particularly sustainable paradigms of transport mode developments.

The rest of the chapter is structured as follows. Section 2 summarizes the concept of sustainability in transport. This is followed by Section 3 where strategies of transport mode to achieve sustainability are articulated. Section 4 presents the determinants of transport mode choice in intra- and intercity mobility. Section 5 concludes with a summary of findings.

Sustainability in Transport

The Brundtland Report of 1987 famously defined sustainable development as “development that meets the needs of the present without compromising the ability of future generations to meet their own needs” (Brundtland Commission, 1987, p. 8). The European Council (2001, pp. 15–16) defined a sustainable transport system as one that: (1) allows the basic access and development needs of individuals, companies and societies to be met safely and in a manner consistent with human and ecosystem health, and promotes equity within and between successive generations; (2) is affordable, operates fairly and efficiently, offers choice of transport mode, and supports a competitive economy, as well as balanced regional development; (3) limits emissions and waste within the planet’s ability to absorb them, uses renewable resources at or below their rates of generation, and uses nonrenewable resources at or below the rates of development of renewable substitutes while minimizing the impact on the use of land and the generation of noise.

The goals of transport sustainability have been summarized into aspects of environmental, social, and economic quality (Gudmundsson et al., 2016). Transport influences the environment both directly and indirectly. Direct influences include energy consumption, land-take for infrastructure, visual intrusion and noise from construction and use of infrastructure. Indirect influences include air and water pollution, and climate change. In terms of social impacts, some are direct (e.g., time waste, safety hazards) while others are displayed in complicated manners interacting with broader societal trends (e.g., transport inequity, social exclusion). Despite the numerous economic benefits brought by transport, it also generates economic costs. For example, traffic accidents and air pollution would cause the loss of life or reduced quality of life, which impose direct costs to the economy regarding lost productivity and lower welfare. Traffic congestion also brings significant costs on the economic developments, for example, through waste of time.

Different modes of transport play a different role in improving the sustainability of mobility patterns. Pomykala (2018) compared different modes of urban transport—bus, rail, car, and motorcycle, concluding that the most sustainable mode in terms of environmental performance (i.e., CO₂ emissions and energy consumption) is public transport. Therefore, there is a clear need to develop transport policies which encourage people to ride the public transport. In the long-distance travel market, aviation is increasingly conflicting the sustainable goals to limit climate change and challenges concerning noise, air pollution, and infrastructure (Gössling et al., 2019). Although aviation supporters have always emphasized the significance of air traffic for employment and economy growth, it is apparent that the increasing dependence on air travel contradicts principles of the United Nations' Sustainable Development Goals, including "Responsible Production and Consumption" and "Climate Action," and as well undermines the Paris Agreement (Scott et al., 2016). The EU for instance is taking actions to reduce aviation emissions in Europe. CO₂ emissions from aviation have been included in the EU emissions trading system (EU ETS) since 2012. Under the EU ETS, all airlines operating in Europe are required to monitor, report and verify their emissions, and to surrender allowances against those emissions. When considering sustainable transport mode for long-distance journeys, railway network is widely recognised (Givoni, 2006).

Strategies of Transport Mode to Achieve Sustainability

Sustainable mobility regarding transport mode falls into two paradigms. First, transport technology advances current patterns of modes by consuming less resources and generating less pollution. Second, sustainable travel behavior targets more sustainable travel mode choices. The latter forms a more holistic approach by recognizing that the sustainable movement of people and goods requires policy interventions to facilitate the use of sustainable transport modes (Sultana et al., 2019).

Transport Technological Advancements

Black (1997) pointed out that the most straightforward approach to enhance transport sustainability is to make the same trips using the same modes more sustainable. Technology-reliant paradigm recognizes that in some countries (the United States, for example) and cities lifestyles are so much revolving around the automobile that this dependency is extremely difficult to alter in the short and medium run (Sperling and Gordon, 2010). These transport technological advancements may include energy efficiency, pollution reduction, alternative fuels, innovated infrastructure, intelligent transport systems, and efficient driving and flying techniques (Kamga and Yazici, 2014). Some transport policies are also made to accelerate technological developments, such as the implementation of low emission zones or the ban of diesel cars by 2030–35 in various cities.

Clean and Energy Efficient Cars

Providing cleaner fossil fuel-based cars to the driving public is important to transport sustainability. In the United States, the Corporate Average Fuel Economy (CAFE) standards aim to increase fuel economy. The European Union also encourages its member countries to pursue taxation policies to promote the purchase of fuel-efficient vehicles. Many other countries similarly take the fuel taxes as leverage to increase the market share of efficient cars. These regulatory mechanisms—requiring pollution control equipment—have considerably reduced the harmful pollutant emissions from vehicles. Hybrid electric power cars, for instance, have the capability of fuel savings by using an electric motor in replacement of combustion engine during multiple stages of driving. Nonetheless, these fuel savings brought by hybrid vehicle operation need to trade-off the increased vehicle costs associated with the increased complexity of the vehicle (Aftabuzzaman and Mazloumi, 2011; Manzie et al., 2007).

Alternative Fuels and Vehicles

Under the Paris Agreement, worldwide nations have set the long-term goal of the reduction of greenhouse gas emissions from 2005 levels by 2050, for example, the United States and Canada 80%, Mexico 50%. In that context, motor vehicles require greener alternatives to fossil fuel. Relevant industries are developing fast on electricity, natural gas, biofuel, and hydrogen fuel in terms of vehicle and fuel production, repair, insurance, and the deployment of refuel stations. However, it is noted that these alternatives to fossil fuel are basically not equally sustainable (Edwards et al., 2004). In addition, the cost of some fuels is quite economically burdensome, either directly or indirectly by the required associative technologies. Wright (2006) investigated the hydrogen economy and pointed out that hydrogen has the potential to be an alternate transport fuel in Australia in the long run. At the same time, Rand and Dell (2005) argued that the development of hydrogen economy poses scientific and technological challenges in the process of production, delivery, storage, conversion and end-use (Aftabuzzaman and Mazloumi, 2011).

Intelligent Transport Systems

An intelligent transport system (ITS) is an advanced technology which aims to provide services relevant to different transport modes and traffic users and enable users to be better informed and make safer, more coordinated, and smarter use of transport networks. For example, vehicle-to-infrastructure (V2I) and vehicle-to-vehicle (V2V) applications will be tools for improved connectivity, and safety for all modes of transport. They enable vehicles to act like nodes on a network and communicate with the surrounding environment. With the evolution of digital technologies—robotics, artificial intelligence, internet of things, high-performance computers and powerful communication networks—vehicles are eventually expected to guide themselves without human interventions. Connected and automated vehicles (CAVs) are among the most heavily researched automotive technologies, offering mobility

solutions which are cleaner, safer and more consumer-focused than ever. New mobility and smart transport business models are also emerging worldwide. Car sharing, bike sharing, and scooter sharing schemes are continuing to gain popularity; electric vehicle charging schemes is a growing market segment, while novel and smart parking solutions are being employed by shoppers and commuters. All these new models may provide opportunities for achieving sustainability in transport.

Eco-Driving and Eco-Flying

Promoting more efficient driving and flying techniques is helpful to improve transport sustainability. A set of driving behaviors and practices—known as “eco-driving”—includes techniques of shifting, braking, and maintaining a steady speed as well as habits such as ensuring proper tire pressure, regular vehicle maintenance, and limiting vehicle cargo (Kamga and Yazici, 2014). To assist these efforts, some newer cars have dashboard displays which show fuel use to help drivers adjust behaviors. Electric and hybrid vehicles are equipped with regenerative braking which gets energy back to the car. In terms of aviation, airlines are working actively to implement operational techniques which maximize fuel efficiency. Taking as “eco-flying,” these strategies include reducing cruising speeds, optimizing flight and descent paths, and employing on-the-ground procedures which reduce fuel waste, local pollution, delays, and traffic congestion.

Modal Shift to Alternate Transport Modes

Another important paradigm for improving sustainability is to promote the use of alternative transport modes, such as active travel (walking and cycling) and public transport (bus, metro, train, etc.). These modes of transport have comparably low or zero fuel consumption with private vehicles. Bouhot (2007) analyzed how efficient public transport consumed fossil fuel in France and concluded that the energy efficiency of public transport is clearly better than other modes. A global study of cities on transport energy by Newman and Kenworthy (2001) evidenced the energy, environmental, social benefits, as well as economic values of sustainable transport, that is, walking, cycling, and public transport. Cities with sustainable transport systems have shown reduced costs on road construction and maintenance, fewer road accidents, better operating cost recovery and fuel-efficiency, and fewer pollutant emissions. Some transport policies have also been developed to result in such a shift, such the Sustainable Urban Mobility Plans (SUMP) in Europe or road pricing schemes in different cities (e.g., London and Singapore).

Urban Public Transport

With growing concerns for transport sustainability, effective and well-organized public transport is regarded as a primary approach which will have an important influence on future urban mobility. In this context, transport demand management policies are thought to be a significant role using a range of services and incentives to facilitate the use of public transport. In many regions worldwide, public transport ensures that non-drivers (e.g., cyclists and pedestrians) have the minimum level of access to daily necessities, in particular given the need for some form of motorized travel in many western countries (Aftabuzzaman and Mazloumi, 2011). The increase of public transport use also brings about societal benefits, resulting in an increase of physical activity and a reduction in traffic congestion and travel times. The impacts of stress produced by traffic congestion have been found to spill over to workplace, leading to decreased work productivity, reduced employment satisfaction, and even absenteeism (Ma and Ye, 2019).

Walking and Cycling

Walking and cycling are two transport modes which provide the opportunity to form a sustainable transport system in the urban areas. They do not generate pollutants, produce no noise, require limited space and result in safety benefits if a critical mass of walking and cycling is achieved. In addition, walking and cycling offer a good form of regular exercise. The association between active travel and health has been largely investigated and is generally recognized (Hinde and Dixon, 2005). Key elements have been variously defined to increase the use of active travel (Pucher and Buehler, 2008). They include land use change, provision of dedicated infrastructure, demand management of motorized transport, development of supportive public transport, and measures to change attitudes (Tight, 2016).

Train

For the intercity mobility, train is generally accepted to be “greener” than its competing modes. An efficient train network is expected to relieve air traffic and highway congestion, make positive intermodal shifts and resilient transport systems (direct effects), and enhance integrated regional economies, environmental friendliness, and urban industrial competitiveness (indirect effects). In recent years, high speed rail (HSR) development has become a global trend and has ushered in “the second railway age” (Hall and Banister, 1993). HSR—which is more energy efficient given it is operated on electricity, and more sustainable than fossil fuel dependent transport systems—has the potential to reduce the amount of short- and medium-distance flights. Due to its speed (250 km/h or higher), HSR can offer shorter or comparable travel times than the flight on some routes and may therefore substitute it (Givoni, 2006). Modern HSR came into operations in Japan in 1964, and in Europe in the 1970s, and are now being planned and built in many countries internationally. As of 2019, 18 countries have developed HSR to connect major cities, with the network amounting to over 52,000 km.

Determinants of Transport Mode Choice

Urban Mobility

Existing studies show that urban travel mode choice is influenced by a range of elements including socio-demographics, built environment and attitudes. Behavioral heterogeneity in travel mode choices is observed, varying by gender, age, household income, driving license availability, education level, private vehicle ownership, and household structure (Buehler, 2011; Scheiner and Holz-Rau, 2007). Li et al. (2012)—investigating travel mode choices in the UK—revealed that the share of car use decreases among older people after their 1970s. In terms of gender, Cheng et al. (2019) found that females depend more on public transport than males in Nanjing, China. Bhat and Srinivasan (2005) moreover noted that travelers with higher income are more apt to travel by car. Using the 2001 American Housing Survey, Plaut (2005) identified that highly educated people make more trips (recreation-related trips in particular) by public transport. Car availability is a decisive predictor of car trips. Finally, travelers from larger households have a lower inclination to use non-motorized modes than those from smaller households (Ryley, 2006).

Furthermore, multiple key attributes of the built environment have been identified to play a significant role in travel mode choice, such as land-use mixture, building density, dedicated infrastructure for cyclists and pedestrians, proximity to public facilities, and transport provisions (Cervero, 2002). Generally, high density and mixed land use encourage people to walk or cycle or use public transport facilities. Dedicated neighborhood design toward walking and cycling facilitates the use of active modes. In addition, the enhanced accessibility tends to positively impact walking. In order to improve accessibility, it is essential to decrease the travel distance to public facilities as well as increase transport network connectivity.

Since the 1990s, the influences of attitudes on travel mode choice have gained considerable attention. Studies show that attitudes may be more powerful predictors of travel mode choice than the conventionally used objective measures (e.g., travel time, distance, or generalized costs). Analyzing the commuting data from Sweden, Johansson et al. (2016) found that attitudes towards comfort, flexibility, and environmental preferences significantly impact modal choice. Heinen et al. (2011) analyzed the impact of commuters' attitudes toward the benefits of cycling (e.g., low cost, convenience, and health benefits) on commuting mode choice. Their findings suggested that attitudinal factors provide additional explanations for commuters' cycling choices.

Intercity Mobility

As with studies on urban mobility, socio-demographics and spatial attributes have been found to influence mode choice for intercity travel. Income is one of the most important socio-economic factors. Private car is in general the mostly used transport mode for all income groups. However, low-income people are more likely to take inter-city train and coach services (Arbués et al., 2016), while high-income people use faster modes more frequently, particularly flights (Llorca et al., 2018). The income effect could also partly relate to the differences in employment status. Students and employees are thought to make more trips and also use a variety of modes, with students travelling more by train and coach and less by air and car than employees. Car availability is also an important factor, negatively impacting the tendency to use train for long-distance commuting, business and recreational trips (Reichert and Holz-Rau, 2015). Other research also documented how spatial attributes impact mode choice for long-distance travel. Access to inter-city transport services is important, where Reichert and Holz-Rau (2015) observed that high accessibility to railway station contributes to the likelihood of performing long-distance trips, in particular by train and flights. Urban population is also found to travel more by train and flights, compared to their rural counterparts. It is noted that both the spatial characteristics at the origin and destination account for the difference in mode choice (Limtanakool et al., 2006). van Acker et al. (2020) indicate that coach travelers are mostly female and students, live in low-income households and in urban environments, and travel mostly for private purposes (not commuting or business).

Summary

This chapter has introduced that transport sustainability encompasses environmental, social, and economic aspects. Different modes of transport have different impacts on sustainability and public transport and active modes are generally thought to be well performed. Two main paradigms are identified to achieve transport mode sustainability: transport technological advancements and modal shift to alternate transport modes. The latter forms a more holistic approach which requires policy interventions to alter individuals' travel mode choice. Furthermore, socio-demographics, built environment (or spatial attributes) and attitudes are discussed to be important factors affecting mode choice in intra- and intercity mobility.

INTRODUCTION

Roger Vickerman

In an increasingly globalized world, despite reductions in costs and time, transportation has become even more important as a facilitator of economic and human interaction; this is reflected in technical advances in transportation systems, increasing interest in how transportation interacts with society and the need to provide novel approaches to understand its impacts. This has become particularly acute with the impact that Covid-19 has had on transportation across the world, at local, national, and international levels. This Encyclopedia brings a cross-cutting and integrated approach to all aspects of transportation from work in many disciplinary fields, engineering, operations research, economics, geography, and sociology to understand the changes taking place.

Transportation is both influenced by, and an influencer of, changes in the economy and society. Increasing speeds have reduced journey times and made the world a smaller place as globalization has affected both where people live and work and from where they source their goods and materials. Increasing volumes of traffic, often on old and life-expired infrastructure, lead to congestion and delays. Constraints on public budgets have led to increasing pressure on the private sector to fund improvements requiring new and innovative financial solutions. While there are clear differences in the nature of the pressures felt in the developed and less developed economies, there is an increasing recognition that in all societies, there is an accessibility problem such that certain groups become disadvantaged by the lack of access to reliable and cost-effective transport. While the problems are clearly multidimensional, research on transportation is often constrained by single disciplinary approaches and this carries over into the practice of transport planning and policy. The Encyclopedia cuts across these artificial boundaries by taking an approach that emphasizes the interaction between the different aspects of research and aims to offer new solutions to understand these problems. Each of the nine sections is based around a familiar dimension of work on transportation, but brings together the views of experts from different disciplinary perspectives. Each section is edited by an expert in the relevant field who has sought chapters from a range of authors representing different disciplines, different parts of the world, and different social perspectives. In this way, the work is not just a reflection of the state of the art that serves as a starting point for researchers and practitioners, but also a pointer toward new approaches, new ways of thinking, and novel solutions to problems.

The nine sections are structured around the following themes: Transport Modes; Freight Transport and Logistics; Transport Safety and Security; Transport Economics; Traffic Management; Transport Modeling and Data Management; Transport Policy and Planning; Transport Psychology; Sustainability and Health Issues in Transportation. Some of the chapters provide a technical introduction to a topic while others provide a bridge between topics or a more future-oriented view of new research areas or challenges. While there is guidance to cross-referencing between chapters, readers are encouraged to explore the tables of contents of all the sections to get a full understanding of the issues. Much of the Encyclopedia was completed before the Covid-19 pandemic and clearly this will have changed the situation in many areas covered by this work; the advantage of this type of reference work is that relevant updates will be possible in future editions.

The Encyclopedia has only been possible because of the cooperation of a large number of people. Robert Noland, Georgina Santos, Xiaowen Fu, and Dick Ettema served as an Editorial Advisory Board identifying possible editors of sections and advising on the overall structure. The Section Editors, Edoardo Marcucci, Kevin Cullinane, Per Garder, Maria Börjesson, Edward Chung, Chandra Bhat, Maria Attard, and Carlo Prato,

carried out the work of identifying potential authors of individual chapters, commissioning these, encouraging authors and reviewing drafts. More than 600 authors and co-authors of chapters are, however, ultimately responsible for the success of this venture. Thanks are also due to the key people at Elsevier, particularly the Publishers, Andre Wolff and Oliver Walter, and the Project Managers, Sophie Harrison and Natalie Bentahar; they have shown exemplary patience over more than 3 years in bringing this work to fruition.

LIST OF CONTRIBUTORS TO VOLUME 6

Maria Attard

Department of Geography, Faculty of Arts, University of Malta, Msida, Malta

Stephen Ison

Leicester Castle Business School, De Montfort University, Leicester, United Kingdom

Lucy Budd

Leicester Castle Business School, De Montfort University, Leicester, United Kingdom

Miloš N. Mladenović

Otakaari 4, Espoo, Finland

Cyrille Médard de Chardon

University of Hull, Hull, United Kingdom; Luxembourg Institute of Socio-Economic Research (LISER), Maison des Sciences Humaines, Esch-sur-Alzette/Belval, Luxembourg

Fiona Ferbrache

CONTENTS OF ALL VOLUMES

<i>Editorial Board</i>	<i>v</i>
<i>Introduction</i>	<i>vii</i>
<i>Contributors to Volume 6</i>	<i>ix</i>

VOLUME 1

Introduction to Transportation Economics	1
Market Failures and Public Decision Making in the Transport Sector <i>Bruno De Borger and Stef Proost</i>	2
Demand for Freight Transport <i>José Holguín-Veras and Diana G. Ramírez-Ríos</i>	7
Cost Functions for Road Transport <i>José Manuel Vassallo</i>	13
Future of Urban Freight <i>Russell G. Thompson</i>	20
Operation Costs for Public Transport <i>Marco Batarce</i>	26
Natural Monopoly in Transport <i>André de Palma and Julien Monardo</i>	30
Freight Costs: Air and Sea <i>Yulai Wan and Dong Yang</i>	36
Transport Production and Cost Structure <i>Ricardo Giesen and Darío Farren</i>	46
The Concept of External Cost: Marginal versus Total Cost and Internalization <i>Sofia F. Franco</i>	56
Value of Time <i>John J. Bates</i>	67
Valuation of Carbon Emissions <i>Svante Mandell</i>	72
Valuation of Travel Time Variability Using Scheduling Models <i>Katrine Hjorth</i>	76

Value of Crowding <i>Daniel Hörcher</i>	84
What Drives Transport and Mobility Trends? The Chicken-and-Egg Problem <i>Nathalie Picard</i>	89
Pricing Principles in the Transport Sector <i>Bruno De Borger and Stef Proost</i>	95
Long-Run Versus Short-Run Valuations <i>Stefanie Peer</i>	102
Value of Noise <i>Jon P. Nelson</i>	106
The Value of Life and Health <i>Henrik Andersson</i>	114
The Value of Security, Access Time, Waiting Time, and Transfers in Public Transport <i>Raquel Espino, Juan de Dios Ortúzar, and Luis I. Rizzi</i>	122
Demand for Passenger Transportation <i>Kenneth A Small and Robin Lindsey</i>	127
Real-World Experiences of Congestion Pricing <i>Charles Raux</i>	134
Distributional Effects of Congestion Charges and Fuel Taxes <i>Jonas Eliasson</i>	139
The Bottleneck Model <i>Dereje Abegaz and Yili Tang</i>	146
Dynamic Congestion Pricing and User Heterogeneity <i>Kathrin Goldmann and Gernot Sieg</i>	150
Economics of Parking <i>Daniel Albalade and Albert Gragera</i>	159
Loss Aversion and Size and Sign Effects in Value of Time Studies <i>Andrew Daly</i>	165
Intertemporal Variation of Valuations <i>James Fox</i>	170
The Rebound Effect for Car Transport <i>Bruno De Borger, Ismir Mulalic and Jan Rouwendal</i>	174
Elasticities for Travel Demand: Recent Evidence <i>Fay Dunkerley, Charlene Rohr and Mark Wardman</i>	179
Parking Price Elasticities <i>Stephan Lehner</i>	185
The Pareto Criterion and the Kaldor Hicks Criterion <i>Harald Minken</i>	190
Social Discount Rates <i>Lars Hultkrantz</i>	195
Cross-Elasticities between Modes <i>Mark Wardman and Jeremy Toner</i>	201
First-Best Congestion Pricing <i>Moez Kilani</i>	209

Ethical Aspects-Can We Value Life, Health, and Environment in Money Terms? <i>Jose M. Grisolia and Ken Willis</i>	216
Car tolls, Transit Subsidies for Commuting, and Distortions on the Labor Market <i>Ioannis Tikoudis¹ and Kurt Van Dender¹</i>	221
Demand Management and Capacity Planning of Airports <i>Stephen Ison and Lucy Budd</i>	227
Dealing With Negative Externalities: Low Emission Zones Versus Congestion Tolls <i>Valeria Bernardo, Xavier Fageda, and Ricardo Flores-Fillol</i>	231
The Rule-of-a-Half and Interpreting the Consumer Surplus as Accessibility <i>Mogens Fosgerau and Ninette Pilegaard</i>	237
Producer Surplus <i>Chau Man Fung</i>	242
The Robustness of Cost-Benefit Analyses <i>Morten Welde and James Odeck</i>	249
The GDP Effects of Transport Investments: The Macroeconomic Approach <i>James Laird and Daniel Johnson</i>	256
The Mohring Effect <i>Hugo E. Silva</i>	263
Public Transport Fare and Subsidy Optimization <i>Qianwen Guo and Zhongfei Li</i>	267
Transportation Equity <i>Rafael H. M. Pereira, and Alex Karner</i>	271
Impact of Transport Cost-Benefit Analysis on Public Decision-Making <i>Niek Mouter</i>	278
Causal Inference for Ex Post Evaluation of Transport Interventions <i>Daniel J. Graham</i>	283
Transport Cost and Location of Firms <i>Adelheid Holl</i>	291
Commuting, the Labor Market, and Wages <i>Jan Rouwendal, and Ismir Mulalic</i>	297
How to Buy Transport Infrastructure <i>Johan Nyström</i>	302
Procurement of Public Transport: Contractual Regimes <i>Andrew Smith, and Chris Nash</i>	308
The Mono-Centric City Model and Commuting Cost <i>Zhi-Chun Li, and Ya-Juan Chen</i>	315
Value of Time in Freight Transport <i>Gerard de Jong</i>	321
The Economics and Planning of Urban Freight Transport <i>Edoardo Marcucci, Valerio Gatta, and Michela Le Pira</i>	326
Incentives in Public Transport Contracts <i>Andreas Vigren</i>	332
Transportation Improvements and Property Prices <i>Alex Anas</i>	337

Transport Infrastructure Effects on Economic Output: The Microeconomic Approach <i>Patricia C. Melo</i>	347
Wider Economic Impacts of Transport Investments <i>Anthony J. Venables</i>	355
Employment Effects of Transport Infrastructure <i>Anna Matas, and Javier Asensio</i>	360
Regulatory Reforms and Competition in Public Transport <i>Didier van de Velde</i>	365
How to Finance Transport Infrastructure? <i>Tiziana D'Alfonso, and Giuseppe Catalano</i>	371
Congestion, Allocation and Competition on the Railway Tracks <i>John Armstrong, and John Preston</i>	378
Public Private Partnership <i>David Meunier, and Emile Quinet</i>	385
Airline Economics <i>Anming Zhang, Yahua Zhang, and Zhibin Huang</i>	392
Privatization and Deregulation of the Airline Industry <i>Achim I. Czerny, and Hao Lang</i>	397
Price Discrimination and Yield Management in the Airline Industry <i>Guoquan Zhang, Colin C.H. Law, Yahua Zhang, and Hangjun Yang</i>	404
Regulation and Competition in Railways <i>Chris Nash, and Andrew Smith</i>	409
Cycling Economics <i>Bert van Wee</i>	414
The Economic Rationale for High-Speed Rail <i>Ginés de Rus</i>	419
Rail Cost Functions <i>Kristofer Odolinski, and Phill Wheat</i>	425
Transport and International Trade <i>Siri Pettersen Strandenes</i>	431
Maritime Economics: Organizational Structures <i>Kevin P.B. Cullinane</i>	436
Port Planning and Investment <i>Jasmine Siu Lee Lam</i>	443
Estimating the Capital Stock of Transport Infrastructure <i>Heike Link</i>	449
The Economics of Reducing Carbon Emissions From Air and Road Transport <i>Olga Ivanova</i>	457
Regulation and Financing of Toll Roads <i>Marco Ponti</i>	464
Are Megaprojects too Transformational for Cost-Benefit Analysis? <i>Tom Worsley</i>	470
Economics of Transportation Safety <i>Ian Savage</i>	476

Cost Overruns of Transportation Infrastructure Projects <i>James Odeck, and Morten Welde</i>	483
The Downs-Thomson Paradox <i>Joel P. Franklin</i>	490
Policy Instruments for Plug-In Electric Vehicles: An Overview and Discussion <i>Jake Whitehead, Patrick Plötz, Patrick Jochem, Frances Sprei, and Elisabeth Dütschke</i>	496
Vertical and Horizontal Separation in the European Railway Sector and Its Effects on Productivity <i>Pedro Cantos-Sánchez</i>	503
How will Autonomous Vehicles Impact Car Ownership and Travel Behavior <i>Patrick M. Bösch, Felix Becker, Henrik Becker, and Kay W. Axhausen</i>	508
Policy Instruments to Reduce Carbon Emissions from Road Transport Computable General Equilibrium Analysis in Transportation Economics <i>Johannes Bröcker</i>	520
Estimation of Value of Time <i>Stefan Flügel, and Askill H. Halse</i>	527
The Taxation of Car Use in the Future <i>Griet De Ceuster, and Inge Mayeres</i>	534
Cost-Benefit Analysis and Other Assessment Techniques: Contrasts and Synergies <i>Paolo Beria</i>	540
Demand for Air Travel and Income Elasticity <i>Jing Lu, Yucan Meng, Changmin Jiang, and Cheng Lv</i>	547
Generalized Cost for Transport <i>Jeppé Rich</i>	555
The Impact of Electric Vehicles on Energy Systems <i>Patrick E.P. Jochem, Jake Whitehead, and Elisabeth Dütschke</i>	560
Uber versus Taxis <i>Georgina Santos</i>	566
Contract Efficiency in Public Transport Services <i>Philippe Gagnepain, and Marc Ivaldi</i>	572
Company Cars <i>Stefan Gössling</i>	580
Transportation Network Companies (TNCs) and the Future of Public Transportation <i>Susan Shaheen, and Adam Cohen</i>	584
Public Transport in Low Density Areas <i>Jani-Pekka Jokinen, Leif Sörensen, and Jan Schlüter</i>	589
Market Failures in Transport: Direct and Indirect Public Intervention <i>Federico Boffa, and Alberto Iozzi</i>	596
The Braess Paradox <i>Anna Nagurney, and Ladimer S. Nagurney</i>	601
VOLUME 2	
Introduction to Transportation Safety and Security <i>Per Gårder</i>	1

The Concept of “Acceptable Risk” Applied to Road Safety Risk Level <i>Claes Tingvall</i>	2
Crash Not Accident <i>Robert A. Scopatz</i>	6
Age and Gender as Factors in Road Safety <i>Marion Sinclair</i>	11
Aggressive Driving and Road Rage <i>James E.W. Roseborough, Christine M. Wickens, and David L. Wiesenthal</i>	17
Aircraft Maintenance and Inspection <i>Alan Hobbs</i>	25
Airport Security <i>Richard W. Bloom</i>	34
Transport Safety and Security: Alcohol <i>James C. Fell</i>	40
Animal Crashes <i>Michal Bil</i>	53
Attenuators <i>Simonetta Boria</i>	63
ATV, Snowmobile, and Terrain Vehicle Safety <i>David P. Gilkey, and William Brazile</i>	77
Automobile Safety Inspection <i>Subasish Das</i>	85
Aviation Safety: Commercial Airlines <i>Clarence C. Rodrigues</i>	90
Aviation Safety, Freight, and Dangerous Goods Transport by Air <i>Glenn S. Baxter and Graham Wild</i>	98
Bicycle Collision Avoidance Systems: Can Cyclist Safety be Improved with Intelligent Transport Systems? <i>Lars Leden</i>	108
Bicycle Infrastructure <i>Rock E. Miller</i>	115
Bicycles, E-Bikes and Micromobility, A Traffic Safety Overview <i>Höskuldur Kröyer</i>	125
Bicycles: The Safety of Shared Systems Versus Traditional Ownership <i>Mercedes Castro-Nuño and José I. Castillo-Manzano</i>	139
Bridge Safety <i>Per Erik Garder</i>	144
Carsharing Safety and Insurance <i>Elliot Martin and Susan Shaheen</i>	150
Carjacking <i>Terance D. Mieth, Christopher Forepaugh, Tanya Dudinskaya</i>	157
Collision Avoidance Systems, Airplanes <i>Ivan Ostroumov and Nataliia Kuzmenko</i>	164
Collision Avoidance Systems, Automobiles <i>Erick J. Rodríguez-Seda</i>	173

Connected Automated Vehicles: Technologies, Developments, and Trends <i>Azra Habibovic and Lei Chen</i>	180
Construction Zones <i>Jalil Kianfar</i>	189
Costs of Accidents <i>Ulf Persson</i>	196
Critical Issues for Large Truck Safety <i>Matthew C. Camden, Jeffrey S. Hickman, Richard J. Hanowski, and Martin Walker</i>	200
Demerit Points and Similar Sanction Programs <i>Matúš ťucha and Kristýna Josrová</i>	210
Driver State and Mental Workload <i>Dick de Waard and Nicole van Nes</i>	216
Drugs, Illicit, and Prescription <i>Rune Elvik</i>	221
Education, Training, and Licensing <i>Matúš ťucha and Kristýna Josrová</i>	228
Elderly Driver Safety Issues <i>Mark J King</i>	233

Introduction to Transport Policy and Planning

Maria Attard, Department of Geography, Faculty of Arts, University of Malta, Msida, Malta

© 2021 Elsevier Ltd. All rights reserved.

In a world dominated by growing cities, increasing population, global environmental change at a scale which is unprecedented, the issues surrounding transport and mobility come to the forefront to support cities and functioning urban areas, mobilize and provide opportunity for populations around the world and unfortunately contribute significantly to the climate crisis. The COVID-19 pandemic which has spread across the world at the time of writing this introduction has also shown the key role of transport in both spreading the contagion as well as supporting efforts to control the virus amidst fears of economic collapse. The changes affected to transport systems during the year 2020 across a number of cities in Europe and beyond, will provide ample opportunities for urban and transport planners in the future to seek better ways of connecting people and places, with less negative impact on the environment and more positive impact on community well being.

The importance of transport policy and planning has never been so crucial, and research in this field is necessary because of the dynamic nature of transport systems and the speed of change experienced in the last decades. Changes that are being driven by technology but not only. The necessity to reduce emissions and the need for a better quality of life, with well being becoming a growing priority for many policy makers around the world, is changing the attitudes and perspectives of urban and transport planners who are moving away from the classic planning models of the 20th century into uncharted territories of liberalized and less regulated transport markets, higher levels of mobilities, greater access to information (big data) and customers, and different travel behavior needs in cities worldwide. Policy making is becoming more reactive to population demands, some choosing more populist approaches, other driven by increasing media and social media polarization, and some moving forward and leading the way toward sustainability and net-zero carbon transport systems.

This section of the Encyclopedia of Transportation deals with transport policy and planning. It provides for a very broad spectrum of topics and subjects which span the policy and planning fields. The number and variety in the articles and topics underline the extensive nature of transport policy and planning, and its crosscutting character with and across other disciplines, both in transport and beyond. The articles include the classical and more basic foundation topics of land use and transport planning, evaluation, project financing, transport demand management, planning for public transport, rail and air transport, transport externalities, safety and security, and goods and freight transport. Others are more focused on elements of transport policy such as parking, with an article dealing specifically with the most recent concepts of the workplace parking levy, taxi services and microtransit in cities, tourism travel, road pricing, and climate change. There are articles which provide for an understanding of planning tools such as the latest developments in accessibility tools, the use of sensors and data in transport planning, multimodality and transport demand modeling tools, and modeling and simulation tools. The need to focus on specific population groups is provided in chapters dealing with elderly mobility, childrens' independent mobility and active travel, community transport, and a look at gendered mobilities.

Furthermore, this section of the Encyclopedia provides for a discussion of topics related to the politics of transport, the role of media, as well as public engagement. All important topics when considering how transport policy is formulated and how transport planning works. The growing importance of transport justice and equity in transport is covered by articles dealing with equity, social and distributional impact assessment in transport, policy and governance, transport for healthy cities, severance, and the importance of walkability, especially in urban areas. The section also includes articles dealing with transport planning in China and the Global South, both considered important in the overall discussions and debates about transport planning in large, but potentially poor cities.

And finally the section would not have been complete without a look at the emerging technologies that are supporting the development of new transport systems and services. These include articles on Mobility as a Service (MaaS), the rise of bicycle and car sharing, electric mobility, autonomous and connected vehicles and the technologies that will support such future modes through Intelligent Transport Systems and infrastructures. Counter to these more future oriented discussions, a chapter dealing with ageing infrastructure is included to highlight the imminent need of transport infrastructures which, like any other infrastructure, fall victim to financial and structural sustainability issues.

There are many other articles not mentioned in this introduction which play a significant role in the future of transport policy and planning. I invite readers to browse through the subjects and also crossreference with other sections of this encyclopedia. In that manner readers will learn to appreciate the breadth of topics and disciplines that make up transport policy and planning.

Workplace Parking Levy

Introduction

Transport Demand Management (TDM) is a catch-all term used to describe a range of strategies and interventions which are designed to influence individual travel behavior and result in the more efficient use of increasingly scarce road space (Ison and Rye, 2008). More specifically, TDM covers a range of measures which aim to address urban traffic-related issues associated with the prevalence of the private motor car as the dominant mode of urban mobility. The negative externality effects of private car use, including congestion, environmental degradation, the inefficient use of land for parking stationary vehicles, skewed economic development, reduced public transport provision and patronage, and increased risk of road accidents, impact all users of the urban space, irrespective of whether or not they use a car. For example, pedestrians are subjected to the impacts of air pollution. TDM measures include not only economic and regulatory interventions but also support for modal substitution and enhanced public transport provision (Table 1).

Imposing a direct charge on users of private cars provides a financial disincentive to car use. Charges can be levied both on mobile private vehicles, through road user charges or tolls, and/or on stationary vehicles that are parked. Regulatory controls on the road space that private vehicles are (or are not) permitted to use when in motion (for example, dedicated bus corridors, high vehicle occupancy lanes, and pedestrianized zones) and when parked are also employed. The regulation of parking policy and the charging regimes that are employed thus form an important component of any urban TDM strategy. Significant areas of land are devoted to car parking spaces in cities world-wide with many of the spaces free of charge to motorists (Burchell et al., 2019). In fact, Shoup (2005) stated that “parking is the single biggest land use in cities”. There is a high cost involved in this land use and since it is often free for office car park users motoring can be seen as more attractive than it would be if charged for so as to meet the full economic cost of providing a space. It is clearly the case that providing car parking spaces free of charge can encourage the use of the car leading to traffic congestion and environmental degradation. The level of traffic congestion can indeed be more severe since commuters will be traveling at morning- and evening-peak periods. While urban authorities are generally able to control on-street and off-street parking provision in multistorey car parks or surface facilities that falls under their direct jurisdiction, their ability to control private nonresidential parking spaces (including those associated with office developments and major employment centers such as hospitals and universities), is far more limited.

The boom in new office development in the UK in the 1950s and 1960s exacerbated this challenge as, at the time, the provision of parking spaces, commensurate with the size of the proposed building, was required to obtain planning permission for the development. For reasons of spatial efficiency and cost, this parking was often provided underground in the basement of the building or, less commonly, on the roof. The perceived wisdom was that if cars could be removed from the public roadway then additional road space would be available for through traffic. However, congestion, directly caused by rising levels of commuter traffic, increased. One of the responses to this was to limit the number of parking spaces permitted at new build offices from the 1970s onwards. However, a large- volume of private nonresidential parking spaces remained over which the local authority had little, if any, control once they had been created.

The purpose of this chapter is to review the factors which led to the formation of legislation to enable the introduction of a Workplace Parking Levy (WPL), discuss the implementation of the scheme in Nottingham and provide insights into the lessons that can be learned from the Nottingham experience.

Table 1 Example TDM measures

Type of measure	Examples
Economic	Road user charges Charges for on-street and off-street parking Subsidization of public transport
Regulatory	Bus Lanes Controls on parking Pedestrianized zones
Travel information	Real time passenger information Public transport website provision
Land use policy	Land use and transportation strategy Park and ride facilities
Travel substitution	Home working Video conferencing

Source: Based on Ison and Rye (2008)

Background

The legislation relating to the WPL can be traced back to the [UK Government White Paper “New Deal for Transport: Better for Everyone” \(1998\)](#). This document advanced the notion that local authorities could introduce a road user charge or a workplace parking levy (or both) to address problems resulting from urban traffic congestion and poor local air quality providing that the revenue raised was hypothecated for improvements in the local transport network. The 1998 White Paper led to legislation in the form of the Transport Act (2000) which detailed the provisions and scope of the WPL and granted powers to local authorities to implement and enforce a WPL (and road user charge) if they so desired. The [Workplace Parking Levy \(England\) Regulations, 2009](#) No 2085 added to the existing legislation with respect to the issuing of penalty charges for noncompliance and the management of this process.

In the aftermath of the Transport Act (2000) 35 local authorities in the UK were interested in introducing either the WPL or a road user charge. However, only one major city in the UK, namely Nottingham, ultimately sought to address the issue of congestion and environmental externalities through introducing a WPL. This imposed a charge on companies who provide more than 10 private parking spaces at the workplace. 20 years later and following Nottingham’s lead, other UK cities including Bristol, Cambridge, Edinburgh, Glasgow, Leicester and Reading plus the London Boroughs of Camden, and Hounslow are reportedly considering introducing similar schemes.

Other than the Nottingham scheme there are a number of schemes, most notably in Australia, of a similar type. [Table 2](#) provides a comparison of the schemes operating in Perth, Sydney, Melbourne, and Nottingham. The Nottingham scheme focuses solely on workplace employer provided parking. The aim of all four schemes is to address the issue of traffic congestion be it as a TDM pricing tool and/or as a means of raising revenue in order to invest in improving public transport infrastructure ([Dale et al., 2017b](#)). [Legorreta and Newmark \(2015\)](#) undertook a review of worldwide parking space levies (PSL). Of the 11 schemes they examined it

Table 2 Parking levy schemes

City	Area covered	General Description	Liable for a charge				Introduced
			On Street Parking	Public Car Parks	Unoccupied Spaces	Small Business	
Perth Parking License Fee	Central Business District (CBD)	All nonresidential parking bays that are in use	YES	YES	NO	NO	1999
Sydney Parking Space Levy (PSL)	CBD + five other outlying business areas	Off street private nonresidential parking, occupied or un- occupied, does not apply to public car parks.	NO	NO	YES	YES	1992
Melbourne Congestion Levy	CBD	All public and private long stay nonresidential car parking spaces currently in use	NO	YES	NO	YES	2006
Nottingham Workplace Parking Levy	City of Nottingham	Occupied private nonresidential off-street workplace parking	NO	NO	NO	NO	2011

Source: Adapted from [Dale et al. \(2017b\)](#)

would appear that only Perth, Sydney, and Melbourne impose a scheme that resembles that of the Nottingham Scheme. As can be seen in [Table 2](#) however, unlike Nottingham it would seem that the Australian schemes include other types of off-street parking spaces. In fact, the Nottingham City Scheme is the only one which is focused exclusively on workplace parking provided by employers. All the schemes primarily focus on addressing traffic congestion be that as a price-based tool or via the revenue raised being used for public transport improvements. Whilst there are cultural, legislative, and geographical differences between Nottingham and the Australian cities, the Nottingham Scheme is similar in respects reflecting elements of policy transfer in developing the WPL in the UK.

The Nottingham WPL

In 2007, the City Council in charge of transport planning and provision in Nottingham, a city of almost 330,000 people in the English East Midlands, stated its intention to introduce a WPL on car parking spaces that are provided by major employers within the city boundary ([Bishop, 2018](#); [Dale et al., 2014](#)). An employer would become liable for the charge if they provided more than 10 parking spaces for use by employees, students/pupils, or regular business visitors. To take account of the fact that one employer's car parking spaces could be located at different sites around the city, the total number of spaces an employer has is considered to be the sum of all liable parking spaces that the employer provides within the Nottingham City Unitary Authority area. Any employer with 10 or fewer spaces is given a 100% discount meaning there is no charge as are emergency services employers (namely Ambulance, Police, Fire and, National Crime Agency), qualifying NHS premises and any space that is used by a disabled motorist displaying a valid Blue Badge. Parking spaces that are used by customers (for example, shoppers visiting retail parks or retail premises) are not defined as Workplace Parking Places in the enabling legislation and are therefore also exempt.

Nottingham City Council began issuing licenses on 1st October 2011, six months before the WPL scheme commenced. The WPL aimed to:

1. Reduce congestion in the morning and evening peak period (which was estimated to cost the city economy £160 million every year in the morning peak period alone) by encouraging employers to reduce the number of parking spaces they provide and limiting the number of parking destination points for employees;
2. Use the hypothecated revenue to fund major public transport improvements, including two additional tram lines linking the suburbs of Clifton and Beeston/Chilwell with the city center, redeveloping the city's mainline railway station by refurbishing its concourse and platforms; and investing in local bus services;
3. Help businesses adopt workplace travel plans and develop 'smarter travel choices';
4. Enhance Nottingham's attractiveness as a location for conducting and investing in business;
5. Be managed in such a way as to not impose any displaced parking issues for communities located immediately outside the WPL charging zone.

Overall, the intention of the WPL was to stimulate regeneration of Nottingham City, provide environmental improvements, support business in developing their travel plans and improving land use, in addition to impacting directly and indirectly on traffic congestion ([Burchell et al., 2015](#)). The WPL was introduced from April 1st 2012 and, from an initial capital outlay of £4 million for development and implementation, generated over £44 million in revenue in the first 5 years of its operation ([Bishop, 2018](#)). The main reason the City Council in Nottingham adopted a WPL as opposed to a road user charging scheme was the speed with which income could be generated for public transport improvements and the relatively low cost of implementation. The WPL scheme and the associated improvements to public transport can be identified as the "WPL package" with each element complementing the others to provide an overall enhanced TDM provision.

Public Acceptance of the WPL

Public acceptance of the proposal was identified early in the development phase of the scheme as representing a potentially significant barrier to implementation ([Frost and Ison, 2009](#)). The scheme was initially opposed by Nottingham-based businesses and sections of the local media for imposing additional costs and bureaucracy on businesses which may damage the city's economy, for being unfair on private motorists who already paid road tax, fuel duty, and insurance for their vehicles, and for the fact that some claimed it would have little impact on congestion.

In recognition of the need to gain widespread public acceptance of the scheme, Nottingham City Council engaged in an extensive public consultation process and sought to promote the health and productivity benefits of better public transport provision. This consultation period involved numerous meetings and focus groups with business leaders and firms within the city as well as commuters, residents, and neighboring local authorities. Extensive discussions about the practicalities of the proposal, its administration, management, costs, and possible charging regimes were conducted. By July 2007, the WPL proposal was sufficiently well developed to permit the Council to hold a week-long nonstatutory "public examination" of the proposals which was led by an independent chairperson and received contributions from 28 stakeholders ([Dodd, 2007](#)). The resulting report, "The Proposed Nottingham WPL, Report of the Public Examination" offered various recommendations, including the need for ongoing business support to offset the cost of the WPL to employers.

The Structure of the WPL Scheme

Every owner or occupier of premises with 11 or more workplace parking spaces within the city boundary has to apply to the traffic authority for a license. Over 3000 smaller businesses, each with fewer than 10 spaces within the city boundary, were exempted but over 500 larger employers were required to apply for licenses. The WPL enforced a principle of maximum vehicle occupancy not exceeding the license. An implementation charge of £288 per space per year was initially levied (a minimum of £3168 per liable firm) with enforcement enacted by a dedicated team of 5 WPL Officers with penalties for noncompliance. Subsequent annual increases in the charge were linked to inflation and the charge for each liable space stood at £424 for the year 2020–21.

By 2017, 5 years after it was implemented; the WPL was raising £9 million a year (at an operating cost of £500,000) and achieving 99% compliance. It was reported that half of liable firms absorbed the charge directly whilst the rest passed it onto their employees (Clayton et al., 2017). The monies raised were invested in local public transport improvements. As a consequence, Nottingham witnessed considerable mode shift from private cars to more sustainable public transport modes. Other impacts have been noted in terms of improvements to the urban environment and public realm as land which was previously earmarked for parking has been converted into alternative residential and commercial use.

Impact of the Nottingham WPL

While the introduction of a WPL does not necessarily result in a reduction in congestion, in the case of Nottingham, Dale et al. (2017b) state that the number of liable workplace parking spaces is positively related to the level of delay. It is, however, somewhat difficult to identify the overall effect of such a scheme given that such schemes tend to be implemented as part of a package of measures, with the revenue ring fenced for the provision of a package of TDM measures. In this respect the Nottingham WPL is no different. Dale et al. (2017a) conclude that “there is no observable negative effect on overall macroeconomic performance associated with the introduction of the WPL”. Overall, the WPL would appear to be of relatively small consideration as part of a business investment decision.

Limitations of the WPL and Lessons Learned

One key issue with any WPL is the equity of the charge. One limitation of the present scheme is that it does not (and cannot) distinguish between commuters who drive within the city boundary in peak periods and those who do not. In addition, it cannot differentiate between commuters who have a suitable viable public transport alternative to the private car and those who do not.

In recognition of this, it could be argued that a conventional road user charge, which levies higher fees on drivers for driving in congested peak periods, could be perceived as being a more equitable way of tackling congestion and poor local air quality. The introduction of real time monitoring and “smart” vehicle density and speed responsive traffic management systems could offer a potential way to address the WPL’s limitations.

Conclusion

In terms of the UK, Nottingham was the first city to introduce a WPL. Its introduction provides important lessons for those authorities thinking of implementing such a scheme, most notably in terms of public acceptance. This is in fact the case with all market-based approaches to addressing the issue of traffic congestion. One thing is clear namely that the increased awareness in recent years with respect to environmental issues both local and global not least in terms of air quality, and climate change, plus the financial constraint public authorities are working under, means that the potential for implementing a WPL will continue to be on the political agenda of many cities. Evidence would suggest that the introduction of the WPL has led to a reduction in the level of congestion over the period 2011/12 and intuitively one would expect this to be the case namely as a result of (1) increasing the cost of commuting to work, if the employer passes on the levy to employees, (2) the number of car parking spaces being reduced, hence the number of termination points, and (3) the enhanced public transport provision. In addition, the enhanced public transport network can be seen to improve the environment within which the business community operates offsetting what can be seen as the cost of the WPL.

Introduction

Of all the principal modes of transport, aviation is the most recent as it has only existed for a little over 100 years. In that timeframe, aircraft have transformed international relations and military engagements, permitted new forms of aerial recreation, international travel, and tourism and created new ways of becoming and being (aero)mobile (see [Goetz and Budd, 2014](#)). Air transport has had a profound impact on the structure and functioning of global society and aeronautical expressions including “autopilot”, “flying high” and “taking off” have entered the cultural lexicon of everyday commerce and conversation.

Air transport describes the use of aircraft for a range of different purposes which can be categorized into commercial, military, and general aviation activities. Commercial air transport describes the use of civilian aircraft, which are available for public use, to fly people and goods between defined origin and destination airports at agreed standards of safety and service in exchange for revenue. Military air transport, in contrast, describes the use of dedicated military airframes (which are not available for public use) to transport military personnel and equipment between airbases and to/from/within theatres of operation. The third category, general aviation, covers the use of smaller and lighter aircraft for recreational, agricultural, medical, and civilian surveillance purposes. In each category of air transport activity, the aircraft that are deployed can be fixed or rotary wing. In the case of general aviation, the aircraft can be both heavier and lighter-than-air (hot air balloons). All three types of activity make use of unmanned aerial vehicles (drones) as well as other specialized aircraft which have been developed to deliver particular performance characteristics in terms of range, capacity, payload, operating costs, speed, maneuverability, aerodynamics, and environmental standards.

With the exception of consumer drones (which can be operated from any location providing the operator acts in accordance with national regulations and local restrictions), all other aircraft are flown between fixed ground-based nodes which have been specifically designed and designated for the purpose of flight. These sites are variously described as being airports (which denote commercial facilities for passengers and/or goods which feature customs and immigration inspection posts), airbases (military facilities at which squadrons of aircraft and/or personnel are based), and airfields (smaller civilian facilities for general aviation use which lack the landside and airside infrastructure of airports).

Irrespective of its size and geographic location, every airport, airbase or airfield must, as a minimum, feature a dedicated runway (or lift off area for helicopters) that has been demarcated and prepared for the use of aircraft landing and taking off. They will also feature an area adjacent to the runway on which aircraft can be parked and serviced between flights. Given the larger size and weight of commercial and military airframes vis-à-vis general aviation aircraft, the runway/s, apron areas and the taxiways which connect them are usually hard surfaces constructed from asphalt or concrete. General aviation airfields in contrast may have grass, crushed cinder or compacted earth runways and maneuvering areas. Most, though not all, will also have an air traffic control facility and tower from which air traffic movements on the ground and within the proximate airspace are monitored and controlled. As such, they are vital nodes in a global air network as they facilitate the interface between ground transport modes and aerial ones and between ground and sky. Given the social and economic importance of commercial air transport to the functioning of the modern world economy (on which see [Bowen, 2013](#)), the remainder of this article focuses on the aerial conveyance of passengers and freight on aircraft which are available for public use.

Commercial Air Transport—Past to Present

Prior to the COVID-19 pandemic, over 1400 commercial airlines transported more than 4.6 billion passengers and over 55 million tons of airfreight between 3800 airports around the world ([ATAG, 2018](#)). The scale of this mobility is far removed from the first international passenger flight which occurred between London and Paris in August 1919 and transported a single passenger. Over

the intervening 100 years, innovations in aircraft design and scientific understanding have enabled a species, which is physiologically unable to fly without recourse to mechanical intervention, to safely and routinely take to the skies.

Rapid advances in aircraft design, aerodynamics, and flight control systems have enabled the construction of progressively larger and more reliable civil aircraft. This has improved the standard of safety and passenger comfort and lowered aircraft operating costs leading to cheaper airfares. In the political and policy arena, regulatory reform from the late 1970s onwards has reconfigured and/or removed many of the restrictive bi- and multilateral air service agreements which structured the early development of air transport operations and opened up more markets to competition (Budd, 2018). This has stimulated innovation in airline business models. The emergence, expansion and evolution of the low-cost airline model which began in the US in the 1970s before being emulated in other world markets (see Budd and Ison, 2014) has transformed the patterns and processes of flight. The availability of lower airfares stimulated demand for air services between underserved airports while the low-cost carriers' "no frills" business philosophy and use of the internet to lower distribution costs has changed consumer purchasing behavior and passenger expectations and experiences of in-flight service. The low-cost airline era intensified already growing consumer demand for flight and air transport has acted both as an enabler and a driver of globalization.

Yet the intensity of current levels of aeromobility have come at a high cost to the environment and local communities whose lives are impacted by high levels of aircraft noise and pollution or the "over tourism" experienced by cities including cities such as for example Venice, Rome, and Barcelona. In order to discuss air transport's societal contributions and challenges, the remainder of this article considers commercial air transport in terms of airports, aircraft, airlines, and airspace. It ends with a discussion of the contemporary challenges and future trends that are likely to occur within the sector.

Airports

It is believed that the word *airport* first entered common use in English during the 1920s. The date and description are important for it was during this decade that the first long-haul routes to destinations in what was then the British Empire were being inaugurated and new inland "ports of the air", featuring customs and immigration inspection posts were developed.

Modern commercial airports are still characterized by their landside and airside features, a distinction that was first established in the early period of flying in the 1910s when it became necessary to separate aircraft maintenance activities from the enthusiastic crowds who flocked to early air shows. Convention dictates that the landside areas of an airport are those which occur between entering an airport and security. These areas are accessible to passengers and nonflying members of the public alike and typically feature ground access interchanges and car parks as well as publicly accessible shops and retail concessions. The airside areas after security control are characterized by duty free shops and departure lounges. The airfield beyond it (here defined as the airside aircraft maneuvering areas) features runways, taxiways, apron areas, and the expanses of grass between them. For reasons of planning, public safety, and customer service, the design of commercial airports is informed by the design parameters and considerations contained within the International Air Transport Association's (IATA) Airport Development Reference Manual (ADRM). The ADRM, which is now in its 9th edition, provides global guidance for airports, architects and developers and stipulates every aspect of airport design from the configuration of taxiways to the allocation of inter-personal space in different subsections of the passenger terminal ecosystem (IATA, 2011).

Historically, most commercial airports were state-owned enterprises which derived most of their revenue from aeronautical sources including aircraft landing fees, parking charges and passenger handling payments. However, the last 30 years or so, particularly though not exclusively in Europe, have seen moves towards greater airport privatization and commercialization. This has not only resulted in many major airports transferring into the private sector but also airport operators deriving ever greater proportions of their revenues from non-aeronautical sources (particularly car parking, retail, and consultancy services). Attracting and maintaining high levels of passenger throughput is thus key to improving economic efficiency, yet as demand begins to reach capacity, bottlenecks and delays can occur which damage an airport's reputation. The incremental development of London Heathrow airport since 1946 is a case in point, as a fourth and fifth terminal were added as demand increased, and proposals to construct a third runway continue to be debated (on which see Le Blond, 2018). Already, a growing number of major airports (including London Heathrow) are operating close to or beyond their original design capacity and demand management interventions including airport slots (see article on airport slots) have been introduced to try and deal with the mismatch between supply and demand. Any form of slot control, however, has its drawbacks and can in certain circumstances effectively prevent or limit market entry by new operators. For this reason, a proportion of slots at the most capacity constrained airports are typically reserved for new entrant operators. At the other end of the spectrum are numerous under-utilized loss-making facilities that cannot attract and retain sufficient custom year-round to make them viable financial propositions. These airports often serve smaller settlements with limited demand and may oscillate between public and private sector owners. A number of commercial airports, including Coventry, Sheffield City, Plymouth, and Blackpool airports in the UK have closed due to lack of demand and competition from neighboring airports in Birmingham, Manchester, Exeter, and Liverpool. Elsewhere, purpose built new airports at Montreal Mirabel, Canada, and Ciudad Real, Spain, did not attract anticipated levels of custom and closed.

Aircraft

Air transport is a derived demand but one that is highly cyclical in nature and one which rapidly responds to changes in global economic health and prosperity. The two principal advantages air travel has over ground based transport modes—superior speed

and the ability to overfly topographical obstacles such as mountain ranges, oceans and deserts with ease—were recognized in the early days of commercial flight and the desire for ever-increased speed and range has resulted in the development of faster aircraft (which culminated in the supersonic Concorde of the late 1970s) and the inauguration of so-called “ultra-long haul” routes which have effectively compressed time and space by enabling long distance journeys to be accomplished more quickly than ever before. As of 2019, the Australian national airline Qantas’s direct B787-9 service between London Heathrow and Perth, Western Australia, offered the shortest connection between the two cities, covering the 14,498 km distance in around 17 h. At the other end of the spectrum, the commercial service between the Scottish islands of Westray and Papa Westray, which can cover the 2.7 km distance in under 1 min, remains the world’s shortest commercial flight.

Although air transport operates on all 7 continents and airlines fly over 45,000 routes between some 3800 airports (ATAG, 2018), the global geographic distribution of flights is unequal and some locations are either only partly connected or are wholly unconnected to the global web of air traffic flows (see Bowen, 2014, 2019). The different demand characteristics and geographical constraints imposed by particular locations has resulted in the production of different types of aircraft from high-capacity long range A380 “Super Jumbos” to narrow-body workhorses including the A320 and B737 and single seat propeller driven aircraft that are capable of operating from unprepared landing strips. Most passenger aircraft can also carry freight, either in the hold or at the rear of the main passenger deck. Specialist quick change (QC) aircraft can be quickly converted from flying passengers during the day to freight at night while fleets of hundreds of dedicated cargo-only aircraft are equipped with strengthened main decks and enlarged side cargo doors (Budd and Ison, 2017).

Airlines

The commercial operators of aircraft, namely the airline companies, can be categorized according to the type of business model they adopt—whether full service, low cost, charter, regional, cargo, hybrid, or specialist—as well as the geographic size and scale of their operations—intercontinental, international, national, regional—their revenue and their customer service and safety reputation (see Table 1).

Irrespective of the business model a carrier adopts, safety is the most important consideration for if an airline is not considered to be safe then passenger demand evaporates, investor confidence disappears, and the airline will not be able to sustain its operations. In a relatively short space of time, aviation has developed from a hazardous mode of travel to the safest form of long-distance transport. Improvements in safety have been swift and welcome and new technological and procedural interventions, including more sophisticated flight controls, heightened training, awareness of the importance of a safety culture, and more rigorous accident investigations have collectively helped to further reduce the risk of flying (see Quddus, 2020).

Given that aircraft can cross international borders with ease, it was recognized that the legal implications of any accident or incident could be significant as there would be a potential conflict of laws. The problem of legal jurisdiction was recognized in the 1920s and in 1929 leading aeronautical nations convened in the Polish capital Warsaw and signed a Convention on air carrier liability. The resulting Warsaw Convention established the international legal mechanism for paying compensation to passengers in the event of injury or loss of luggage. This international convention was followed in 1944 by the Chicago Convention which set in place the framework for the post-1945 development of international commercial aviation. The Convention also established a series of Standards and Recommended Practices (SARPs) which covered issues including carrier licensing, airport facilities, air navigation, and security (ICAO, 1944).

Given the importance of air transport to global society, commercial airlines and airports vulnerable to terrorism and illegal activity. As a consequence, the aviation security regime has been progressively tightened and new screening technologies have been introduced to identify the presence of prohibited items in passengers’ hold and hand luggage as well as on their person and in consignments of cargo (see Trembaczowski-Ryder, 2020). These interventions have imposed financial costs on the sector and have led to delays and consumer dissatisfaction.

As passenger numbers have grown and airlines have sought to lower their costs and improve the efficiency of their operations, many of the functions associated with reservations, check in and flight transfers have been automated and consumers encouraged (or obliged) to use selfservice technologies including online check-in, automated bag drops and digital boarding pass readers. The rise of automated processes has had significant implications for employees and passengers (not all of whom are able to use or wish to use the automated equipment) as well as the airlines themselves who must ensure the security, integrity, and reliability of their systems.

Table 1 The principal types of commercial airline operator

Full service carriers (FSCs) are characterized by their international network, use of major airports, mixed aircraft fleet, provision of different cabin classes, frequent flyer programs and their range of inflight products. They typically have high levels of customer service and high levels of fixed and operating costs.
Low-cost carriers (LCCs) in contrast only provide what is necessary for safe and efficient flight. Costs are kept low by only operating one type of aircraft, flying to cheaper and less congested secondary or regional airports and providing lower levels of customer service.
Charter operators sell their seats to tour operators and fly to popular seasonal “sun and ski” destinations from regional airports.
Regional operators typically fly smaller aircraft on lower demand routes between smaller airports. Their cost base is higher than an LCC and the passenger demand is more modest.
Hybrid operators combine elements of FSC, LCC, Charter and regional operations.

Airspace

One of the areas of air transport that is often overlooked in conventional academic studies of the sector is the (air)space in which aircraft fly. Unlike road and rail vehicles which have to follow a defined track and ships which can only sail between ports, aircraft are theoretically free to operate in three dimensions. However, in reality, the airspace that is available to commercial air traffic is limited by the provision of military or otherwise restricted sectors of sky into which commercial aircraft cannot enter. In the years leading up to 1900, the aerial realm was not subject to any degree of ownership or control but as soon as aerial vehicles from one state began accessing the skies above another, debates about airspace ownership and control commenced in earnest.

The British Government was the first to declare that all airspace above the United Kingdom and British overseas colonies, dominions and mandates, was sovereign territory. Taking its cue from maritime law, it was agreed that in the case of coastal states, airspace sovereignty would extend for 12 nautical miles offshore and vertically upwards to a predefined altitude. This meant that foreign aircraft had to obtain permission to access another country's airspace. Until the late 1930s, all aircraft navigated visually with reference to the ground and pilots followed clear visual markers such as roads, railway lines, and canals.

As air traffic volumes grew over time, increasingly complex regulations and air traffic management systems were introduced to safely and efficiently manage the flow of air traffic (on which see [Budd, 2020](#)). The most visible manifestation of this aerial network are the air traffic control towers which act as the command and control posts of the aerial transport network. In some instances, the towers have been designed with architectural flourishes that attest to the traditions and/or aspirations of the city or nation that hosts them. Other visual manifestations of the air traffic network are high-altitude contrails created by aircraft in the cruise, circling stacks of aircraft waiting to land at capacity constrained airports and the low altitude approach and departure tracks flown by arriving and departing aircraft. A key challenge of airspace management thus now concerns the environmental impacts of aircraft noise and emissions.

Challenges

As a consequence of burning nonrenewable fossil fuel in the form of kerosene in their engines, the world's commercial aircraft fleet (which now numbers almost 32,000 units) generate in excess of 600 million tons of carbon dioxide on international flights as well as large quantities of climate warming water vapor, nitrous oxides, and particulate matter (see [ICAO, 2019](#)). At a local level, aircraft operations generate noise and degrade local air quality around airports, creating odors and emissions which impact on human health and wellbeing. Although individual aircraft are quieter and more fuel efficient than previous generations, technological improvements are not keeping pace with growing consumer demand. Despite innovations in sustainable aviation fuel, including biofuels derived from biological feedstocks, advanced biofuels derived from residues and waste, and electrofuels (also called power-to-liquid or synthetic fuels) which are produced by capturing carbon dioxide from the atmosphere, the high cost and lack of production capacity mean that attempts to decarbonize aviation through fuel innovation are currently limited.

In recognition of this, market-based measures including the EU emissions trading system and ICAO's CORSIA scheme (which aims to limit future aviation CO₂ emissions to 2020 levels), have been introduced as a way of making the polluter pay for their cost of their carbon emissions. Such interventions are, however, unlikely to have a major impact on their own and more dramatic demand management measures may be required. Evidence suggests that growing numbers of consumers are voluntarily choosing to limit the number of flights they undertake, actively seek out more sustainable ground-based public transport modes such as high-speed rail, or cease flying altogether (see [Higham and Font, 2020](#)).

Future Trends

Predicting the future of a sector as dynamic as commercial air transport is fraught with difficulty. Nevertheless, some trends are becoming evident and are likely to continue into the near future. Continued regulatory reform is leading to greater freedom of market entry and exit. Market deregulation is characterized by a wave of market entry as new airlines seek to build a presence in the market. This rapid growth phase is quickly followed by a period of consolidation as airlines are bought up, merge with rivals, or leave the market. This process is leading to the emergence of a relatively small number of carriers who are dominant in their respective markets and who have developed a particular operating niche. The global airport sector too is also undergoing a period of transformation. Commercialization is driving development of nonaeronautical revenue streams while privatization is leading to greater levels of investment by overseas airport operators, foreign pension plans and overseas sovereign wealth funds (see [Graham, 2018](#)).

As far as aircraft technology is concerned, it would appear that passenger demand is driving the development of longer-range and more fuel efficient twin-engine widebody aircraft including the Airbus 350XWB and Boeing 787. The closure of the A380 assembly line, with final deliveries scheduled for 2021 ([Topham, 2019](#)), indicates at the likely direction of the market for aircraft. At the other end of the spectrum, drones and unmanned aerial vehicles are being explored as potential forms of future urban air mobility and such machines have already been used to test deliveries of medicines and small packages. Although talk of the widespread future use of urban air taxis seating one or two passengers is at present arguably premature, but if the cost and safety case can be made then there is every possibility that some form of aerial taxi service may be introduced in time. More far-fetched, perhaps, is the possibility of commercial space travel and the development of vertiports (airports for vertical take-offs) for reusable space vehicles.

Conclusion

For the passenger, the journey of the future is likely to be characterized by even greater levels of automation and customization. Indeed, the impact of the COVID-19 pandemic notwithstanding, the drive for greater personalization and customization of the travel experience (driven by more sophisticated processing power and big data) continues. At the same time, growing consumer awareness of the environmental impact of flying may alter individual consumer's purchasing and travel behavior and, in the absence of a step change in technology, some form of transport demand management (TDM) incorporating the pricing mechanism may be required to suppress consumer demand to more environmentally sustainable levels. This will have significant implications for future air transport policy and planning as the need to "right fit" airport infrastructure and airline business models to a rapidly changing commercial environment will become more acute.

Emerging Technology as a Lens for understanding MaaS

Mobility as a Service (MaaS) is as a powerful and value-laden rhetorical vision of complex socio-technical system for mobility transition that is currently redrawing responsibility and innovation boundaries across societal sectors. Over the following sections, we will attempt to define MaaS through the lens of emerging technology (ET), which as opposed to a variety of societally embedded technologies, has a set of specific properties listed below (Collingridge, 1980; Jasanoff, 2016; Rotolo et al., 2015).

- During the foundational stage, ET is open to further development, having associated uncertainties, prominent (re)distributive impacts, fast development pace, and coherence of the assemblage.
- ET development faces a dilemma, as on the one hand, we are unable to estimate the changes from ET until it is fully formed and embedded in society, while on the other hand, changing a technological development trajectory is very difficult once the technology is fully formed.
- In reflection about desired ET outcomes in the future, we tend to discount harms as more speculative, rather than equally uncertain benefits.
- ET is coconstructed through (ideological) visions and rhetoric, usually only by the few, simultaneously framing the societal challenge and technological solution, with intention to persuade, as well as align the activities of different actors and, crucially, attract funding and publicity.
- ET has interpretative flexibility, where technology working is the result and not the cause of it becoming a successful artifact, and the success of a technology is often assessed through the lens of particular social groups, even if the use is intended for a wider society.
- ET development is often happening through experimentation with the actual artifacts, helping in building a transition pathway for ET from niche to regime.
- Partially influenced by path dependence, ET development trajectory is often significantly influenced by previous lock-in decisions around synergetic technologies, while it generally develops through nonlinear pathways, aided by convergence and assemblage with a multitude of socio-technical aspects.
- Inter- and intraorganizational learning processes depend on strong and loose social networks with multiple types of actors, coconstructing understanding, vision, and evaluation of the performance of the innovation as well as the needs for improvement.
- ET often challenges institutional landscape, structures, and patterns of interaction among actors in unanticipated ways, resulting in redistribution of roles, responsibilities, and power, while often facing an institutional void as well as distributed (ir)responsibility in hybrid institutional networks.

MaaS as Evolution of Transport System Integration

Even if many of the same or similar subconcepts have existed before in the mobility domain, the discourse around MaaS was first introduced in 2013–2014, based on the Go:smart project in Gothenburg, Sweden, and Sonja Heikkilä's masters thesis at Aalto University, Finland (Heikkilä, 2014). That thesis defined MaaS as "a system, in which a comprehensive range of mobility services are provided to customers by mobility operators." Here, we can already see that framing MaaS depends on integration, an important historical concept for user centrality in mobility systems. In fact, the pursuit of increased integration in mobility systems by relying on complementarity of different transport modes has been going on for decades, previously also driven by

Intelligent Transport Systems discourse and deployment. With the socio-technical changes in the recent years (see “Socio-technical Convergence around the Current MaaS Vision” Section), the integrative vision of MaaS relies not only on infrastructural and operational integration but also on informational and transactional integration of mobility services. The user is expected to receive information, book, and pay for a choice of different mobility services by accessing such “one-stop-shop” or “mobility platform” via mobile phone applications or other digital interfaces. Avoiding a binary understanding of MaaS implementation, Lyons et al. (2019) define six levels of MaaS integration, in addition to Sochor et al. (2018), who also mention policy integration:

1. No integration: no operational, informational, or transactional integration across modes
2. Basic integration: informational integration across some modes
3. Limited integration: informational integration across some modes with some operational and/or transactional integration
4. Partial integration: some journeys have full informational, transactional, and operational integration
5. Full integration under certain conditions: some but not all available modal combinations offer a fully integrated experience
6. Full integration under all conditions: full operational, informational, and transactional integration across all modes and all journeys

At the center of MaaS vision is not only the concept of integration but also a dialectic with the contrasting concepts of personalization and customization. Besides the integrated choice of different transport options, MaaS vision also includes an increasing reliance on new transport modes, vehicle sharing, on-demand ordering, and other customization aspects. As opposed to “pay as you go” approach, which could include dynamic pricing, an emerging alternative are bundles/packages including a range of transport modes that users can subscribe to. With sunk cost of paying up front to save later, as with mobile phone contracts, the packaging idea is that such pricing alternative would have lower unit costs and play a role in behavior change. As mentioned in the Heikkilä’s definition, MaaS architecture would have to rely on a mobility intermediary (i.e., operator or broker) layer, in addition to operational/infrastructural (e.g., vehicles, terminals, right-of-way), transactional (e.g., booking, payment, ticketing), and informational (e.g., journey planning, en-route info) layers of interoperability. The initial idea of the mobility intermediary is that such company would be responsible for mobility service distribution, by brokering between users and service producers from whom it buys services on behalf of current and future users (Hensher, 2017). In principle, there could be multiple mobility intermediaries in the same open market that could be established beyond existing administrative borders, similar to mobile phone roaming, and positioned as “optimizers” from both end-user and transport system perspective.

Anticipated Positive Implications for the Current MaaS Vision

Overall, MaaS vision includes an assemblage of interdependent promises to citizens, cities, as well as the private sector, centered on the transition toward a more sustainable “postcar” mobility system. With its interpretative flexibility, this assemblage of promises enables fluidity of MaaS conceptualizations for interpretation depending on its context. One could say that MaaS promises everything, for everyone, by sounding intuitive, understandable, and attractive. From the user perspective, MaaS is supposed to provide a convenient alternative to the private car, relying upon availability of well-integrated transport modes, useful and usable information, and easier payment and billing transactions. Such a shift from ownership toward access to an attractive combination of transport modes includes reduced cognitive efforts for users, enabling convenient door-to-door trip-chains with transfers between modes, as well as departure, mode choice and routing suggestions based on personal preferences (e.g., safety, time constraints, different capabilities). Further customization of mobility services for different travel needs (incl. persons with reduced mobility) would go hand in hand with changing preconceptions about transport modes through positive experiences, and related long-term change in mobility habits and societal norms (e.g., acceptance of electric vehicles).

The expectation of seamless multimodal travel across modes, time and space, combining different trip categories currently in existence, is expected to lead to increased efficiency of the entire transport system. Simultaneously, the expectation is that transport planning and policy institutions will also undergo a transition toward more experimental and agile processes, reconsidering the role of incentives for transition in mobility habits as boundaries of different transport modes eventually fade away. Moreover, the pursuit of system efficiency is assumed to be easier if underpinned with data bonanza about user preferences and behavior. Some of these expectations about system performance could be general across the globe, but could also have particular instances (e.g., increasing the use of mass transit). In addition to the overall improvement in the distribution of accessibility, current MaaS vision is anticipated to have positive implications on environmental sustainability by encouraging higher use of noncar and shared-vehicle modes. Similarly, reduction in private car ownership and use would result in better utilization of land use, such as reduced parking areas, as well as indirect effects on safety and liveability of urban streets, which also positively contributes to city image. Furthermore, the interdependent set of promises focuses on creating a digitally based business opportunity for the private sector, by opening new market domains and being a testing ground for new service models aspiring for international markets. Ultimately, for some, the current MaaS vision might be even a concept beyond mobility, to include booking payments for other everyday activities (e.g., through personal calendar integration), thus aiding to a truly society-wide disruption.

Socio-Technical Convergence around the Current MaaS Vision

Beyond the above aspects of the current vision, MaaS is at the convergence among several socio-technological trajectories, involving a multitude of factors in dynamic interaction. The backbone of technological convergence are long-term technical developments and standardizations, such as development of information and payment interfaces, opening of data (e.g., routes, timetables), interoperability of back-end systems and application programming interfaces (APIs), development of new vehicle features, operational design for near-real-time demand-responsiveness and trip combining for some modes or defined areas (Haglund et al., 2019), as well as strategic changes in transport network structures (e.g., trunk-feeder) and associated land use (Weckström et al., 2019). In the background of these technical developments are general technological trends in sensing, communication, and processing technology, Internet and smartphones, unlocking of data access and improving data quality, providing real-time information, and more secure booking and payment systems. Ultimately, these technical developments are continuing the blurring of boundaries between alternative transport modes.

Besides the technical developments, there is a range of societal trends and evolving ways of life in and beyond the mobility domain, coevolving together with the MaaS vision. Several of these trends are specific for urban environments, such as the population increase, reduction or delay in car ownership, and changing patterns of travel both spatially and related to trip purpose or mode (e.g., reduced number of shopping trips due to online purchases, fewer trips by car, more cycling trips). These urban trends are accompanied with wider societal trends such as an increase in smartphone ownership and digital literacy, political importance of the climate crisis (contrasted with lagging transport decarbonization), uncertainty of long-term employment and income, trust in digital transactions, and proliferation of the so-called sharing economy. The sharing economy aspect is particularly important for the arguments around suboptimal vehicle and urban asset utilization, underlined with social movements for peer-to-peer asset sharing and crowd-sourcing of data, exemplified with higher availability, convenience and affordability of ride hailing services. These transitions are occurring in parallel with more general shifts in urban and regional governance, including more public-private collaborative initiatives; redefining role of the nation-state and strengthening of lower levels of self-government; increasing diversity, variation, and even asymmetry of governance; increasing marketization of the public domain; and shifting rationales for intervention. In particular, the transport sector is experiencing higher emphasis on servitization and more flexible regulation, aiming for promoting openness that should provide testing grounds for new business models. Finally, wider ranges of decision makers and market actors are highly favorable of technological smartness and innovation policy focus on transport technologies, as evident in relation to connected and automated vehicles.

Networked Multi-Actor MaaS Innovation Processes

MaaS is not solely an app or the value concept of service packages, or even the revenue streams that are defining the emerging business model (e.g., current MaaS companies rely on large budgetary losses), but it is a set of organizations, legislation, and other aspects, which collectively serve to lock a technology into society. Thus, the multitude of factors in dynamic interaction outlined in the previous sections develop in interactions between a multitude of networked actors (Wong et al., 2020), engaged in semistructured interorganizational (un)learning. Some of these actors are traditional transport sector actors (e.g., transport operators, data providers, technical solutions providers, national and EU authorities, consulting companies, unions, marketing companies), while some previously fringe actors are changing their roles (e.g., automotive, oil, insurance, or tourism companies), and new actors are also entering the sector (e.g., telecommunication, ICT and big tech companies, retail companies, real-estate developers). Simultaneously, the role of users is changing toward a higher degree of presumption, while new public-private partnerships are being established (e.g., MaaS Alliance in Europe). As previous business models are being challenged, there is an ongoing attempt to shift away from being a supplier of technology to being a provider of mobility services, following the logic of financial viability and profitability for mobile phone markets. Certainly, academic communities have their role in the ecosystem too, exemplified with the fact that several Transportation Research Board committees have mentioned MaaS in their recent centennial papers. These changes in actor constellations are also underlined with expectations from the public sector to be enabler of change and provider of favorable conditions, while responsibility for service development is supposed to be with the private sector. These changes are contrasted with a premise of an open ecosystem, where all transport operators are supposed to offer the same pricing schemes, data, and APIs access to all willing mobility intermediaries. In turn, mobility intermediaries are supposed to be an organizer that cooperates, uses data, and manages the ecosystem.

Ongoing changes in actor constellations and their associated roles do not only mean entrance of new actors, but also redistribution of power and responsibility among the multiactor network, where some organizations are even supposed to disappear, along with associated jobs. In contrast to the MaaS vision, the reality of ecosystem formation in the field remains different. For example, current transport regulation remains highly mode specific and operator-focused rather than user-focused. Similarly, there is a very limited number of MaaS pilots around the world, often with limited scale implementation. Despite the assumption of cooperative and interconnected ecosystems, bringing together organizations providing the means of travel, cooperation is not necessarily advancing in practice (e.g., reluctance of transit operators to engage with MaaS companies). Such lack of cooperation is underpinned with an institutional void and organized irresponsibility that emerging technologies often face. This means that none of the current

institutions has a full understanding or control of undesirable consequences associated with technological constellations. In turn, the resulting distributed responsibility for transition management and technological development limits individual and institutional accountability. An example of such distributed irresponsibility is a full commercial model in small and disconnected markets where everybody agrees with everybody, without there being a single organization with a mandate and interest to take a role of promoting interoperability and cooperation.

Effective cooperation among such established actors with a variety of institutional cultures and often-diverging objectives faces traditional challenges around resistance and inertia of multi-actor innovation processes. Incumbent regime change through disruption relies on the expectation of changes to governance, regulation, and procurement procedures of transport system supply-side developments, as well as changing demand-side developments in terms of the preferences and behaviors of individuals and organizations. In addition to the questions of service procurement rules and revenue flows, cooperation depends on agreements on adequate service pricing, structures of funding programs, policy coordination, as well as possible reduction in some responsibilities (e.g., advertising). Research from Sweden has been proposing a specific solution for the institutional void challenge, by adding a layer of mobility integrators between MaaS operator and transport service provider, who would be responsible for technical, business, and process facilitation, acting as impartial clearinghouse platforms (Smith et al., 2018). Nonetheless, successful cooperation still highly depends on negotiation processes, where trust building and transparency of decision processes remain central ingredients for deliberating between specific wishes and unified solutions.

Unanticipated Negative Implications from the Current MaaS Vision

In contrast to many anticipated positive implications from the current MaaS vision, there is a potential danger that if MaaS comes to fruition, the only fulfilled promise is the one for private sector actors (Pangbourne et al., 2020). At its core, there is challenge with the simultaneous promise of freedom for the users and efficiency on the system level in the context of simultaneous demand in transport networks with finite capacity. Even if the idea of user centrality sounds intuitively positive, there are many currently unanticipated but possible negative implications for users themselves. For example, users will be responsible to judge if MaaS offers provide value for money, which might be more cognitively challenging if the number of choices increases significantly while aiming for customization. These cognitive aspects might be further underlined with the choices around routing, accounts based on social networks, feedback provided on mobility plan execution, or service add ons based on usage trends. Similarly, there could be perverse incentives (e.g., loss aversion) leading people to generate additional discretionary trips to match the package size and avoid the feeling of regret from not maximizing usage. Moreover, discrepancies between travel expectations and experienced level of service might be negatively affecting meanings of trip activities, and other everyday practices beyond mobility, especially if people start seeing through the intentional nudging of their behavior. Thus, there might be a dangerous redefinition of (mobility) commons that could degrade norms of civility. Such changes in expectations can also relate to changes in daily activity spaces, and norms around walking and cycling. For example, given the fact that individuals should undertake a minimum level of daily physical activity to maintain their well-being, current MaaS vision has little reflection about potential replacement with sedentary, shared vehicle modes.

Beyond the above effects on the users themselves, there could be wider questions of equity and technological gentrification. From the current examples, we can see that MaaS concepts are mainly focusing on commuting and business trips, not accounting for existing obligations in transport legislation, such as special user groups. If MaaS becomes a sole access point to geographically bounded transport networks, it is important to ask what happens to those excluded from that newly enclosed system. Such exclusion can be due to affordability, technological availability, technological aversion, or even dissent. For example, MaaS's reliance on registration and use of digital accounts might further exclude social groups experiencing difficulties in handling new technologies or having access to banking, especially older groups or those in the Global South, associated with poverty or lower education level. Furthermore, tying all mobility services to a specific pricing scheme could lead to further transference of existing monetary inequalities, causing further distributive injustices. Finally, an essential set of negative implications revolves around the traditional equity questions of digital technologies, such as cybersecurity, privacy (Cottrill, 2020), and explainability, especially if underlined with aspects of data monetization and biased profiling (e.g., strong identity verification needed for service customization).

An additional aspect to underline is that current visions of MaaS establish user relations mostly on the individual level, failing to acknowledge that current problems are large-scale emergent phenomena arising from the aggregate of our individual activities and preferences. Thus, emergence of systemic effects could also include various undesired consequences, especially in relation to pollution and energy consumption. In fact, it is plausible that a reduction in personal car ownership could be accompanied with an increase in the on-demand vehicle fleet or vehicle kilometers traveled, in order to meet demand. Here, we quickly run into an old question of market monopolies in multiactor systems. With the loss of institutional capacity coupled with resource constraints in urban governance, it might be tempting for many cities to let MaaS "take care of it all," resulting in divestment and erosion of public transport services, especially in smaller markets. Going back to resulting user travel experiences in such context, there is a related question of legal liability and consumer protection, and who is responsible to provide redress if problems arise. Furthermore, we must particularly note the reliance of MaaS on the new ability to generate and utilize Big Data, and thus establish power position

through data enclosure and monetization schemes. Essentially, MaaS has the potential to create a new market by selling data analysis to many different actors, including other private companies, such as retailers. Thus, geographic MaaS monopolies might have to be guarded against, as the first-mover MaaS providers could block new ones from entering the marketplace through developing new entrance exclusion mechanisms related to data ownership or exclusive actor relationships. In this situation, in the case of lack of alternatives, single MaaS operators could constantly raise mobility prices to the end users, with little recourse from those users, and with the possibility of the raised income being taken as profit by the MaaS brokers rather than distributed among the transport operators.

Above challenges could be further mutated by a significant legal uncertainty around contracting, overambitious implementation schedules, missing intraorganizational procedures (e.g., on behalf purchasing), and significant investment efforts for API interoperability without sharing efforts. In this context of organizational change and consequent power and resource redistribution, there are associated risks for implementation, especially related to procurement of services, and impacts on labor market. Beyond these systemic market effects, there could be negative implications from power imbalances on degrading trust, both by citizens toward organizations and in those social networks involved in interorganizational innovation processes. In these situations, legislation that does not fully understand the complexities of everyday innovation activities could easily push different sector organizations into conflicting positions. Such conflicts, even if challenging in themselves, are even more dangerous if they end up degrading interorganizational affects, thus essentially limiting the boundaries of anticipation and willingness to dedicate necessary time for interorganizational learning among those individuals participating in innovation processes.

Toward Responsible MaaS Innovation and Institutional Transition

In addition to all the above possibilities and challenges, the ultimate question that MaaS brings to the table is reflectivity about innovation processes and institutional transition around emerging mobility technologies. From the implications above, it should be evident that systemic change needs systemic understanding of a wide range of factors and their interdependencies. With such uncertainty and complexity, we need to consider new pathways for speculative thinking concerning mobility futures in more responsible innovation processes. Wider system redesign for transition as opposed to cannibalization and enclosure of the current system forces us to ask questions about our innovation policies, investment flows, and objectives of wider societal governance. Simultaneously, we will have to keep on remembering that human ends are not static, but heterogeneous and dynamic set of capabilities, behaviors, and values. Here, we cannot try to streamline innovation processes by narrowing the interpretation for everyday mobility technology (Mladenović et al., 2019). Furthermore, innovation processes around MaaS will have to face a question of Universal Basic Mobility, aiming to include procedures for defining fair distribution of access and experiences, or at least a minimum safety net for those at risk of exclusion. In general, such value-sensitive innovation processes cannot overemphasize speed for regulative development, as it might be counterproductive for implementation activities themselves.

At the center of responsible MaaS innovation debate is a need to avoid depolitized normative foundations in deciding about technological emergence. Potential repolitization of technological development for enabling wider organizational and societal learning requires that debate moves away from narrowly defined expert circles, avoiding the Kehoe problem of building path dependence based on limited knowledge. For innovation to flourish, citizens need to be established as full participants in the envisioning process, alongside networks of actors from different societal sectors. Transparency and open participation of decision processes can also rely on developing open-source standards on the functional requirements for MaaS operation. If tailor-made solutions for interoperability are to be based on developing trust across social networks of innovation, hiding key details behind commercial confidentiality cannot be the power lever for private sector to control interorganizational learning. Moreover, such innovation processes cannot have dominant focus on technical development and anticipated positive effects, while avoiding questions of wider (re)distribution of consequences or solidifying existing societal inequalities. Here, we will have to recognize that debate might lead us to conclude that we need to leave behind some institutions and values, which can only be decided in a democratic process. Such processes for continuously responsible innovation will have to rely on governing piloting and experimentation efforts, and considering new governance levers, such as data governance. Stemming from the recent General Data Protection Regulation, aspects of data collection, storage, and multiway sharing across actors, as well as potential commercial transactions, have to be considered as part of a governance toolkit. Ultimately, it will remain important to continue understanding how does evolving web of promises around MaaS capture and divert (or not) strategic attention of the policy community.

Biography

Miloš N. Mladenović is an assistant professor at the Spatial Planning and Transportation Engineering Group, Department of Built Environment, Aalto University. Miloš has obtained his BSc in Transport Engineering from the University of Belgrade, Serbia, and his MSc and PhD in Civil Engineering from Virginia Tech, USA. In addition, he has held a visiting research position at the Spatial Planning and Strategy chair, Delft University of Technology, the Netherlands. His current research interests include assessment of emerging mobility technologies, and development of decision-support methods. His previous and current teaching responsibilities include a range of courses in transport systems policy, planning, modeling, management, and design. Finally, he has been the organizing chair for Aalto University Summer School on Transportation since 2015.

Bicycle Sharing

Bicycle sharing is an automated service providing shared-use of a bicycle fleet, typically within a dense urban setting, allowing short duration one-way trips from an origin to another location. Since 2005 technological innovation of an older concept combined with public, political, and corporate appeal made these systems common in larger cities, especially within the global North. As a new form of public transport typically implemented within public space, bicycle sharing has been a visible and relatively uncontentious public policy at a time of health, environmental, and equity challenges. This article describes the origin of bicycle sharing, their variations, recent growth and diversification, outcomes, and critiques.

Bicycle sharing is referred to using a variety of names. Bicycle sharing systems (BSS), schemes, services, or programs and public bike share (PBS) or hire, or similar variants, are some of the most common, but misnomers to some degree. Most BSS are not publicly owned or operated, nor is sharing strictly taking place (Belk, 2010). The “sharing” term likely came from an adaptation of car sharing (Shaheen et al., 1998), already using the term since the 70s explicitly, such as Ipswich’s 1977 Share-a-Car service. The use of “sharing” links BSS with the sharing and social economies’ positive connotations of social justice and community solidarity (Moulaert and Ailenei, 2005). Debate regarding the use of the term, or what is part of the sharing economy (Acquier et al., 2017), replicates debates about the contested use of shared space by BSS (Chan et al., 2018). More adequately descriptive terms exist, such as “self-serve bicycles” (France) and “hire bikes” (UK). While the term bikeshare is commonly used colloquially, within the literature BSS is common and will be used throughout this article.

Variations

What constitutes a BSS has become increasingly broad as new business models have appeared. Most commonly, BSS refers to automated bike-access through kiosks, docks, or the bikes themselves, allowing personal bicycle use for, depending on the case, relatively short trips between stations or within an area. The BSS principle relies on multiple users of the bicycles and is priced accordingly to encourage short trips. Punitive pricing schemes exist to discourage longer duration trips (Figure 5). Membership, which is integral to the BSS concept in order to link users’ identity or credit cards with their accounts and the bicycles they are

Figure 1 Clockwise, from the top left, examples of station-based, dockless, hybrid and electric bicycle sharing systems in Vancouver (CA), Manchester (UK), Cardiff (UK), and Luxembourg (LU), respectively.

entrusted with, have a range of costs, free durations of use, and affordances. Most BSS are unique combinations of complex relationships between diverse companies, actors, business models, local laws, system and cycling infrastructure, city and membership contracts, and transportation services and cultures. As these unique systems make generalizing difficult, statements refer to the more prevalent. The most common division between BSS types are those systems commonly referred to generically as bikeshare, which are station-based and dockless.

Stations

Station-based (SBSS) schemes constrain user trips to start and end at stations but generally allow unlimited free trips of a duration, typically, inferior to 30 or 45 minutes. While a smartphone may be practical to find stations, if unfamiliar with the city, a more likely use is to search for a station with available bicycles or docks, near the trip origin and destination respectively. The popularity of SBSS predate smartphone adoption, therefore is not required to use the system. These systems typically rely on bicycles (Figure 1) which can mate securely with docks (Figure 2), preventing, to a certain degree, theft and vandalism. Some systems use more conventional, but flexible, locks that can enable “piggybacking” locked bikes at full stations (See Cardiff image in Figure 1). Additional measures, such as component incompatibility with commercial bicycles, discourage theft. Stations consist of groups of docks, typically, controlled by a kiosk (Figure 3), that can offer the possibility to register, dispense RFID keys or cards, report damage or necessary maintenance, and display account information. Kiosks vary from providing additional services and information points, to requiring interaction in order to check out a bicycle. Importantly, kiosk backs can serve as advertising billboards. Checking out a SBSS bicycle typically requires interaction with the kiosk, dock, bicycle, a combination of these, or all three.

Dockless BSS (DBSS) users access bicycles almost exclusively through personal smartphone applications, allowing the start of a trip wherever a bicycle is available, and end trips anywhere within a demarcated, geofenced, zone (See Figure 4). Geofences are restrictive, limiting deposit of bicycles for legal, operational, and cost-effectiveness reasons, among others. Unlike SBSS, membership costs are typically trivial but users usually pay to unlock the bicycle and for each additional minute or longer time-segments (e.g., 20–30 min, see Figure 5). Some DBSS, such as in Cologne, Germany, could be checked out by calling operators from payphones for lock combination and to report the deposit location of the bicycle after use (before GPS was common).

Figure 2 Examples of station-based and dockless bicycle sharing systems components used to lock and secure bicycles.

Although, BSS are typically discretized into a dichotomy, a variety of hybrid systems exist, with overlaps and differences to station-based and dockless systems. Hybrid (HBSS) systems usually have bikes similar to DBSS but the requirement that bikes be used between stations (also called hubs) that may be no more than paint on the ground (sometimes called havens) or an operator provided bicycle rack. Some systems allow leaving bicycles outside hubs for an added marginal but nontrivial cost (e.g., some SOBI schemes).

Operators

The operation or provision of a BSS consists of an organization, often private, but potentially a nonprofit, private advertiser, municipal government, university, or transportation authority (DeMaio, 2009), maintaining, rebalancing, repairing, providing call-centers, and other aspects, such as marketing and administration, of the service. Rebalancing of bicycle distributions, which goes by many other names as well, is the process of dispatching field workers, and their carrier vehicle, effectively, potentially based on complex optimization algorithms, to achieve desired spatiotemporal distributions of bicycles. This process can be contentious (Médard de Chardon et al., 2017) in terms of desired outcomes, but has other under-recognized aspects, such as creating BSS spatial usage patterns that are not representative of demand. In line with the shared economy aims of unlocking trapped capital constrained in personal ownership (Acquier et al., 2017), rebalancing of BSS bicycles maximizes revenue by relocating bicycles to increase intensity of use. This process has familiar outcomes of capital accumulation: the inability of workers (who may live outside BSS coverage area) accessing the service, having precarious part-time or seasonal contracts without access to health care, low wages, and increased service provisionment in areas of higher urban density (and income).

Ownership

Bicycle and station BSS infrastructure is mainly owned by operators, especially in Europe where advertiser operators are more common, or host cities. Despite the appeal for cities to own and control infrastructure, the complexities of technology patents, and integration can make municipal ownership a burden. The inability of a city to expand a privately owned BSS by a company that has no such desire can be as constraining (e.g., Washington's 2008 SmartBike DC, see Klein, 2015) as the inability of enlarging a municipally-owned BSS with discontinued patented technology (e.g., Seattle's Pronto).

Figure 3 Kiosks are used exclusively by station-based systems to, potentially, register or dispense new memberships, check-out bicycles, report faults, and complete other queries.

Figure 4 Examples of station-based and dockless bicycle sharing information systems.

Figure 5 Cost structures for a selection of larger systems. Note most trips last less than 30 minutes. Membership prices are not included. *Source: Data source: bikeshare-research.org.*

Through technological or contractual leverage, BSS operators can determine or strongly influence BSS outcomes. Growth of this new mobility technology has been largely constrained within a relatively small diversity of companies providing BSS operations and technology (e.g., Uber, Lyft, Tencent, Alibaba, and JCDecaux owning, to some degree, Jump/Lime, Motivate, Mobike, Hellobike, and Cyclocity, respectively).

There exists a large number of smaller companies providing diversified services beyond the classic BSS models. Ownership of most BSS, like any specialized and patented technologies, limit owner independence, repair potential, and cost-effectiveness. Station-based systems are particularly vulnerable with the coupling of docks and bicycles requiring one system for “network effect” of potential trips to be realized.

Revenue

Advertising revenue has been the motivation, purpose, and cause of early BSS growth in Europe since 1998. Facilitated by technological innovation, a resurgence in the popularity of cycling, concerns for environmental sustainability, health, equity, and road congestion, BSS promoters regularly promote the systems as solutions. Despite claims of benefits, a clear BSS goal is often absent (Fishman et al., 2015; Ricci, 2015), preventing evaluation or, as is the case of advertiser provisioned systems, displaying the hypocrisy of sustainability narratives contradicted by consumerism promotion. Such schemes allowed outdoor advertising companies, such as Clear Channel and JCDecaux, to expand their offerings and markets by advertising to, and servicing, the urban privileged (Nitschke, 2015). Separating potential cycling benefits of BSS from the detriments of associated advertising have been challenging to publicly communicate (Tironi, 2014).

Aside from advertising billboards (Figure 3), advertising is also common on bicycles, through station branding, smartphone applications, and system sponsorships, targeted to the desired demographic. Additional revenue sources are municipal and federal grants and loans, membership fees, penalty fees, and the sale of user travel data (Duarte, 2016; Spinney and Lin, 2018; Waes et al., 2018). Penalty or extended-use fees are incurred by members exceeding trip lengths beyond the 30 minutes or so free period. In some situations, such as in Minneapolis, visitors, and recreational users, with short-term memberships and fees, have generated roughly two-thirds of revenue. Despite common claims of being self-funded, public subsidy for BSS is common in North America.

Branding has become an integral part of positioning BSS as sophisticated, fun, healthy, and green, to be promoted locally and externally (McCann, 2013). Conjointly, sponsors or service provisioners have also associated their own brand implicitly, through association, or explicitly, to the naming and styling of the systems (e.g., colors). Further, advertisers offer the opportunity to potential clients to green their brands by placing ads on BSS kiosks or adjacent while targeting a desirable demographic.

Pricing

Membership types have diversified from being strictly of various durations (e.g., day, week, month, year) to also providing different fee structures depending on bicycle type (e.g., manual or electric) and desired “free” period length (e.g., 30, 45, or 60 min). Memberships for DBSS, which were present in the 2017 wave of systems, are now typically free, trivial, or credit toward services.

However, DBSS typically charge a fixed fee at the start of trips and per additional minute. Electric DBSS, (eDBSS) typically have more expensive rates (Figure 5).

In addition to temporal fees, there exist spatial fees. Ending a trip away from a station and performing “out of hub locking” for HBSS typically has added costs (e.g., Hamilton, Canada, and Berlin, Germany). Leaving a bicycle outside of the geofenced service areas, for HBSS and DBSS, incurs high economic or social credit penalties.

Access and Affordances

Rather than sharing, BSS replicate renting, especially for DBSS, and membership models. While this paper focuses mainly on the mainstream systems of this strict definition, there are other bicycle models providing alternative affordances. Alternative cycling as a service (CaaS) models exist (Petzer et al., 2019) based on peer-to-peer renting (e.g., Spinlister), leasing (e.g., Swapfiets), and long-term BSS-like service (e.g., OV-Fiets), but only in a few countries which also have high-cycling modal share (e.g., Netherlands, Germany, parts of Belgium) and where mainstream BSS tend to have less of a presence. These services, just like BSS, vary between (implicit) goals of profit maximizing and facilitating cycling policies, and are priced accordingly. Long-term regional BSS, such as OV-Fiets, are integrated with public transport to allow rapid multimodal trips at trivial cost but the added constraint and responsibility of returning the bicycle to the origin.

Aside from the different systems providing variance in access and affordances, there are concrete BSS spatial, temporal, and economic accessibility factors. While all BSS constrain access spatially, based on availability of stations or a service zone, many also do so temporally, closing during nights and winter periods. Rather than strictly based on decreased demand, seasonal closures are preventative measures due to the negative effects of salt and snow plows, degrading or damaging the bicycles, performance issues with locking mechanisms, and the need to shovel free the bicycles from the snow.

Membership prices, for SBSS vary largely for annual subscriptions, from the trivial to the equivalent of the purchase of a low-end bicycle. Municipal governance decisions impact whether a BSS maximizes private profit generation or access to a bicycle. Many North American systems, but not most, provide discounted memberships to low-income residents. It is unclear to what extent this demographic group takes advantage of such offers in terms of membership or number of trips.

The usability of BSS at the scale of the bicycle and checking it out can alter access time from seconds to over a minute. Some systems require multistep procedures of interaction through the kiosk, such as presenting your card, pin, and designating the bicycle desired followed by unlocking the dock and adjusting impractical bicycle seat-height mechanisms. Necessary interactions also vary according to membership or short-term users.

Finally, additional accessibility constraints exist due to the availability of lights, for night use, range of seat heights, fenders for use in wet conditions, and alternative bicycle designs for people with disabilities.

Contracts

Contracts between municipalities and operators, who may also be the technology or patent owners, can have large impacts on BSS outcomes. Generally, contracts formalize the cost and period of service, number of bicycles and stations, and service levels in terms of rebalancing, and call centers, but also stipulate the provision of open-trip data, monthly reporting, and annual user surveys. Contractual details can have large impacts (and costs for the operator), such as the number of working and active bicycles on the street and the frequency, duration, and location of outages, where stations are full or empty. In some situations the ability or cost of future expansion has not been defined, resulting in constraints. Advertiser provisioned BSS agree to quantities of advertising panels of specified sizes. Barriers can arise, due to station kiosks sometimes doubling as advertising panels (Figure 3), if a municipality desires BSS expansion into neighborhoods where provisioners have little interest advertising.

Service cost contracts can fluctuate heavily according to municipality negotiations. While many advertiser provisioned BSS in Europe were provided without cost, in some cases, such as in Aix-en-provence, France, in addition to advertisements the municipality paid high rates for the services. Contractual opacity and constraints between conjoined advertising, BSS, and even bus shelters, have encouraged a disassociation of advertiser-provisioned services.

Integration

The integration of a BSS, spatially and in terms of quality of service, facilitates its use. While some cities facilitate integration with rail service, others avoid it due to the difficulty in satisfying demand or desire for BSS use for purposes other than daily commutes. At the street network scale some cities may more prominently allocate space for BSS, such as at intersections, while others relegate them to side-streets. While stations may replace on-street parking or lanes, many systems' stations are located on sidewalks. Either option can cause dissatisfaction with sidewalk and road users and local residents and businesses. In selecting either option municipalities communicate underlying values, such as the importance of cycling over other modes, that in some cases contradict suggested BSS outcomes while also creating tension between cyclists and other mode users (e.g., pedestrians or drivers). Municipal mediation strategies include charging operators rent to utilize parking space for stations (for a service which the city may be paying—indicating a performative practice).

Actors

The planning and deployment of BSS creates interaction between a variety of actors with complimentary and competing interests. While heavily influenced by the urban regimes of mayors, decision makers, technocrats, and large companies, wishing to attract the skilled or “creative” classes, some BSS deployments have also had to deal with public scrutiny. Within these actors are project

promoters seeking political gain, economic profit, or belief in BSS as a means of providing equity, health benefits, environmental sustainability, or improved quality of life. While well-placed promoters, such as mayors, can shape the narrative of BSS outcomes by championing their benefits, they can also facilitate and expedite their deployment. As BSS occupy public space physically, where many other public policies or private initiatives do not, they provide platforms for criticism and discontent. Some cities, particularly in North America, provide public participation in the BSS planning processes. Whether these initiatives result in pacification rather than democratizing project planning is unclear. Regardless, the diversity of actors, their interactions and tensions, shape BSS deployment, and outcomes.

Governance

Station-based systems, which largely popularized BSS, were often championed by mayors (DeMaio, 2009) but also bound by municipal requirements to collaborate in order to gain advertising rights and access to public land and, depending on the system, utilities. Dockless systems however (e.g., Mobike and Ofo) operate with much less constraint. Governance, the application of state power, of DBSS has only recently been enforced in some cities, resulting in bicycles being impounded or requiring permits and payment of fees. In Seattle, for example, operators pay a \$50 annual fee per bicycle, among other requirements.

There has been little governance surrounding where BSS are and are not being provided, in terms of stations but also the bounds of DBSS service zones, which results in unequal access to the services. Municipalities, who frequently champion BSS, desire the systems to be self-funding, have high use, and be labeled as a success, facilitating justification of the service being located in denser more exclusive urban cores.

The less formal relationships between companies and municipalities can result in reduced collaboration and unpredictability of future system presence, making planning a challenge. Rather than municipalities integrating DBSS for a desired urban mobility framework, these innovations are shaping transportation, with governance, adaptation and regulation being carried out in a reactionary manner. Bicycle sharing has largely been dictated by private and advertising interests shaping transport decision-making toward capital-maximizing and individualized travel with little public input.

Cycling governance has sometimes been adjusted to accommodate BSS. As BSS riders have lower rates of helmet use than personal bicycle riders (Zanotto and Winters, 2017), helmet laws were recognized as a barrier to use. Some cities have repealed their helmet laws proceeding BSS deployment (Fishman, 2015).

History

The evolution of BSS is regularly discretized into three generations. The social and technological innovation of new system types has been driven by various factors: protest to air pollution and consumerism, the affordances of an accessible and worry-free bicycle, the battle for advertising market share, and most recently, access to market niches. Efforts to define the attributes of a fourth generation BSS regularly overstate the importance of incremental changes. Rather than a linear evolution, a diversification of system technologies and service types has occurred.

Free Bicycles

Bicycle sharing, as a concept, was founded in 1965 in Amsterdam where the counter-culture movement *Provo*, within a context of urban renewal facilitating increased automobility and decreasing cycling (Ploeger and Oldenziel, 2020), protested against air pollution and consumerism by creating the witfietsen (White Bikes) (Beatley, 2000; Teun Voeten, 1990). Activists, in an initiative led by Luud Schimmelpennink, gathered bicycles, painted them white, and placed them on the street for free public use. The initiative successfully provoked police, who confiscated many of the unlocked bicycles through the use of a bylaw. Despite this the initiative demonstrated that an alternative model of bicycle access was possible. Schimmelpennink, believing in the concept, went on to develop and influence, among other things (Ploeger and Oldenziel, 2020), BSS growth for many other systems of note (e.g., Copenhagen and JCDecaux's systems) facilitating the rise and popularity of BSS in the mid 2000s.

Other cities mimicked the White Bikes, such as in Portland (US), but struggled in achieving a durable presence. La Rochelle, in France, due to strong mayoral support, managed to deploy and maintain a system for a longer period and of greater scale than others.

Coin-Deposit Bicycles

In 1995, a coin-operated system was developed in Copenhagen. Users could place a 20 Kroner coin (equivalent to \$4.50 today) to check out a bicycle, which would be returned upon locking at their destination. The Copenhagen system is the most well-known of this generation due to its size (2000 bicycles at 150 stations) and length of operation, until 2012 (17 years).

Neither the first nor second BSS generations became more common than oddities. While the vulnerability to theft and vandalism is often named as limiting factor to their growth, and as the following generations have to some degree similar problems, constraints where likely also the (un)popularity of cycling and lack of economic incentives and a viable business model.

Marketing Innovation

The technological development of automating the association of users to checked-out bicycles using smart-card technology in 1996 in Portsmouth, United Kingdom, enabled conventional BSS. However, it is market innovation that popularized BSS through advertising competition in Europe. In 1998 in Rennes, France, outdoor advertising furniture giant JCDecaux lost its bus-shelter contract to Clear Channel due to the latter offering a BSS in addition to bus shelters. JCDecaux rapidly developed its own BSS offering

Figure 6 Third generation station-based bicycle sharing systems growth in terms of bicycles at launch (or earliest available statistic) in Europe, North America and China. Source: Data source: *bikeshare-research.org* and, for China, *Zhang et al., 2013*.

in order to remain competitive. As a result Lyon (2005) and Paris' (2007) requests for offers were contested. Driven by desire to maintain market share and facilitated by technical innovation, Lyon and Paris became lighthouse projects popularizing the BSS concept while also creating new markets for out-of-home advertising.

While growth in Europe precedes that of China and North America, the scale of Chinese system sizes fast outpaced the rest of the world combined. **Figure 6** shows the growth of third generation SBSS in terms of number of bicycles at launch. The figure highlights the large number of small systems that are present in Europe and North America, relative to China.

Europe's BSS growth, while having some stability in system continuity, was impacted by the 2007–2008 economic crisis resulting in some smaller systems being poorly funded or closed, particularly in Spain and Italy. Germany was very different than other countries. Students initiated a DBSS in 1998, requiring the use of pay phones. It was purchased by the German railway company and expanded nationally. This system grew to have a large presence in some cities while also being only present at railway stations in many other cities, and in some case limiting the deployment of larger systems (Nitschke, 2015).

While advertiser-provisioned BSS dominated the deployment of larger systems in Europe, in North America SBSS were largely provided by various combinations of technology providers, infrastructure ownership, and operators. Opposing desires between the municipality and operator (Clear Channel) for North America's (Washington DC) first BSS trial in 2008 (Klein, 2015) provided a cautionary demonstration of advertisement-provisioned limitations, making them an unpopular choice.

While many systems have been deployed in North America, mainly in the United States, a very large proportion are small. **Figure 7** depicts SBSS growth in number of systems and bicycles. The figure contains limitations due to some small BSS missing. Data for DBSS is more difficult to summarize due to their ephemeral nature, barriers to data accessibility, and reduced public collaboration.

China's BSS growth, 2008–2011, was largely station-based, operated by nonprofit enterprises working in collaboration and with government support. Prior policies of "progress" toward the automobile and to decrease bicycle use in the 90s, were being reversed with plans for extensive bike lane development. The growth of DBSS in 2015 contrasts with previous systems, by being privately owned and operating without municipal support. Similarly to, for example, the US and UK, the barriers to BSS use in China are the same as the barriers to cycling, mainly safety concerns and lack of adequate infrastructure. There were 12 BSS in China in 2012 (Zhang et al., 2013) while North America had 26 (Shaheen et al., 2014). China however had over 180,000 bicycles while North America had fewer than 14,000.

Dockless and Electric

The 2014–2017 period was turbulent for BSS. Rather than an evolution to a fourth generation of BSS, a diversification of service and technology types appeared that are not superior but filling market niches. In Europe some early service contracts expired and were

Figure 7 North American third-generation station and hybrid bicycle sharing system growth in terms of bicycles at launch (or earliest available statistic), grouped by technology provider. Source: Data source: bikeshare-research.org.

not renewed, such as in Paris, JCDecaux's showcase city. While advertiser provisioned BSS, more common in Europe, were always in the marketing business, in North America large BSS-related companies transitioned from the transport sector to ownership by investment and technology companies. Monetary constraints, and related conflicts, impacted the largest North American BSS technology provider and operator, PBSC and Motivate, respectively, creating uncertainty (e.g., Seattle) and opportunity (e.g., SOBI) (Médard de Chardon, 2019). In China, in 2016, the rapid growth and expansion of DBSS, such as Mobike and Ofo, flooded Chinese streets, rapidly transforming positive associations to problematic (Gu et al., 2019). In 2017, large numbers of these bicycles appeared in North America and Europe with little local government collaboration or adequate preparation. Vandalism was once again blamed as a cause of the exit of these DBSS, but declining funding, competition, supply chain problems, lack of local knowledge and municipal responses, through fees or impounding of bicycles, challenged their permanence. While DBSS may have greater potential to scale (Waes et al., 2018) due to reduced costs, other costs appear to be prohibitive to long-term viability (Gu et al., 2019).

During this period the hybrid BSS appeared in North America, mainly through SOBI, but other technology providers appeared, such as the French Smoove, promoting its "smart-bikes" which provided no additional affordances over regular SBSS. Riding on the popularity of smart cities, reference to smart-bikes has been used by a variety of BSS. Additionally, the functionality of DBSS, in some cases, are resembling more SBSS due to increasing requirements that free-floating bicycles be placed within delineated spaces due to conflict with sidewalk users. Earlier fears of SBSS being supplanted by DBSS have been unrealized.

Bicycle sharing novelty has been a large driver of its growth, explaining, since 2015 roughly, the rising number of electric BSS (eBSS) that provide a more luxurious service (and image). This investment in eBSS has impacts in terms of coverage potential and number of concurrent users relative to a mechanical BSS, given a fixed investment, mimicking similar debates between bus versus tram or light-rail services (Walker, 2012).

Outcomes

Generalizing the outcomes of BSS or evaluating their potential is challenging due to the large number of variables (see Variations above). There exists a large variability of usage rates (Médard de Chardon et al., 2017) determined by many factors (Faghih-Imani et al., 2017; Sun et al., 2018; Wang and Akar, 2019). The most consistent across BSS studies is that riders are more likely male, white, wealthier, younger, more educated, owning a bicycle, and employed, than the general population (Bauman et al., 2017; Fishman, 2015; McNeil et al., 2017; Nickkar et al., 2019; Ricci, 2015; Wang and Akar, 2019). The fundamental cause of this is BSS being located in exclusive spaces, such as university campuses, urban cores (Hosford and Winters, 2018; Ursaki and Aultman-

Table 1 Modal share replacement of bicycle sharing systems from member surveys. Variable member usage rates prevent modal shift impact prediction from total trips counts or distances. Sources: Fishman et al., 2013; Fishman et al., 2014; Fuller et al. (2011), LDA Consulting (2016); Murphy and Usher (2014); and Winters et al. (2017).

Case study	Driving	Bus	Rail	Walking	Mode shift (%)		New trip
						Private cycling

Vancouver	6	19	4	54	9	9	2
Washington	5	14	21	39	3	3	2

* Bus and rail combined

Hall, 2016), and the roads themselves, facilitating access for those with economic means and willingness to cycle within hostile spaces.

Who uses BSS determines where beneficial outcomes are located. At the individual user level, BSS provide convenience but with limitations. While granting use of a bicycle, potentially electric, for a one-way trip without fear of theft and responsibility for maintenance and storage, there are trip or membership costs, the added weight of a durable bicycle, potentially incompatibility in terms of size and (dis) ability, requiring travel to or from the bicycle, and the uncertainty of having access to a bicycle nearby and a free dock at the desired destination. Additionally, convenience or limitations are relative to individually-accessible alternative modes for the same trip and societal barriers to cycling (Golub et al., 2016).

Usage rates of BSS are frequently used to determine the potential impacts on health, environmental sustainability, equity, and even congestion mitigation. The modal shift rates from other transport to BSS is helpful in evaluating outcomes (Table 1). More than simply replacing modes, BSS can complement or substitute modes depending on other factors.

Findings of outcomes are mixed in regards to reducing carbon emissions (Audikana et al., 2017; Fishman et al., 2014), improving health (Murphy and Usher, 2014; Zhang et al., 2013), gender and social equity (Garrard et al., 2012; Hoffmann, 2016; Ricci, 2015; Wang and Akar, 2019), and facilitating a larger cycling modal shift (Bauman et al., 2017; Hosford et al., 2019; Pucher et al., 2011; Ravalet and Bussiere, 2013). Despite the abundance of new transportation data BSS provide, abstracting clear causes and outcomes is still challenging, with small groups of BSS users potentially biasing overall outcome perceptions (Winters et al., 2019).

The benefits of BSS are often confounded with those of cycling, causing statements by urban regime actors, BSS technology and service providers, and even academic literature as normative opening statements to be largely unfounded (Médard de Chardon, 2019). Despite this, BSS policies are innovative for being pro-cycling, where few existed before. Additionally, they help to raise awareness and acceptance of bicycles, normalizing casual and utility cycling, due to their presence (Goodman et al., 2014).

Critique

While bicycle sharing systems are convenient and enjoyable to use for a privileged subset of the population, overstated benefits, usually the result of conflating cycling and BSS, are heavily promoted by those associated with the systems. Specifically, health, environmental sustainability, congestion reduction, and equity benefits are exaggerated. Most BSS are of such a size that they have little impact at the urban scale of transport, making them tokenistic performances. Similarly to the BSS deployments accompanying Republican (Cleveland, 2016) and Democratic (Charlotte, 2012 and Denver, 2008) National Conventions in the United States (Marshall et al., 2015), the Olympics and World Expo in China also motivated BSS launches (Zhang et al., 2015).

While BSS serve some commuters and recreational users, alternative, more cost-effective, efficient, and established practices are more proven to yield greater cycling modal share and all their associated benefits (Buehler et al., 2016). While it is unlikely BSS will bring about a societal transition, it may exacerbate existing inequalities by providing uneven accessibility improvements, resulting in increased tensions and self-policing (Spinney and Lin, 2018).

The recent growth of eBSS, in replacing mechanical BSS, supports perspectives of these systems being urban symbols of sophistication for self-promotion (McCann, 2013), interlocal competition (Peck and Tickell, 2002), and tools of gentrification (Hoffmann, 2016) due to their providing a luxurious experience at greater cost to fewer people than their predecessors.

Finally, the rapid growth of BSS can be explained by a confluence of self-serving interests, facilitated by a metaphorical and literal neoliberal vehicle for entering and expanding markets (Duarte, 2016), like other smart-city initiatives (Martin et al., 2018), utilizing unfounded narratives of sustainability, health, and social equity (Médard de Chardon, 2019). The evaluation of BSS have been too often using hard to evaluate metrics rather than opportunity costs, revealing the lack of clear BSS objectives, and greater benefits of alternative policies.

Concepts for Further Research

Bicycle sharing research frequently provides case-specific insight. While some trends are apparent, such as the dominant type of BSS user, generalizations are challenging due to the many variations between BSS (see Variations above). In the growing sectors of the sharing economy, micro-mobility, and mobility and cycling-as-a-service, BSS are one of the most widely adopted. Despite this, its efficacy at providing clear outcomes is unproven.

The ease of BSS data access and aggregation has made the domain attractive for quantitative analysis in an effort to describe urban mobility. This explains the richness of statistical and regression work on the topic. Dockless BSS conversely due to lacking data access are much more opaque. Regardless, there is a clear need for more nuanced and qualitative analysis of BSS' governance and interactions between its actors. The technical aspects of BSS, relating to technology patents, contracts, and their lock-ins, have had large impacts on the direction and outcomes of key BSS projects (e.g., Rennes, Paris, Seattle) that help reveal the motivations and procedure within urban regimes and markets.

While there has been extensive study of theoretical bicycle rebalancing optimization, very little research has explored this process in practice that has important control over system outcomes. Additionally, little work has explored why BSS are not frequent or having high usage in countries and cities with high-cycling modal shares, raising the question of whether they serve as necessary tools for a cycling transition. If they are inadequate tools for modal behavioral change, it reinforces their outcome as being an additional, largely privatized, accessibility option for the urban hyper-mobile.

Finally, in a world of institutional automobility, little work has studied how BSS governance relates to challenging this problematic state. Despite their promotion and sometimes dubious goals, BSS still appear to be "fit" in urban spaces, without challenging the pervasive facilitation of cars.

Light Rail

Light rail transit (LRT) describes a range of urban rail transit systems running largely on exclusive rights of way within city centers and between city centers and their suburbs. Light rail operates mainly at street level but may include elevated and underground sections as well as tunnels, and can operate on converted rail routes. Light rail is electrically powered, usually from overhead cables, but since APS (*alimentation par le sol*) ground system was pioneered in Bordeaux (which opened 2003/2004), ground system supply has been used in other cities, particularly in central locations where heritage or aesthetics demand protection of buildings or urban features such as bridges. Light rail usually features level-boarding and pre-paid fares and provides an enhanced quality of transit in terms of service speed, frequency, safety and reliability, as well as a modern design (see Figs. 1 and 2). However, light rail is varied and includes forms more commonly referred to as, for example, modern streetcars (e.g., Portland Streetcar, Oregon, US), driverless light metros (e.g., Copenhagen Metro, Denmark; Dockland's Light Railway (DLR), London, UK), supertrams (e.g., Sheffield Supertram, UK) and tramways (e.g., Toulouse, France). There is no well-established boundary between these different forms and sometimes the terms are used interchangeably.

More broadly, light rail is often distinguished from other transit modes such as buses and heavy rail, though they may share certain features. Commonly noted points of distinction include light rail's fixed infrastructure versus buses' flexibility (often expressed as permanence versus temporality), its image and "the assumption that trains are sexy and buses are boring" (Hensher, 2016:289), and light rail's reputation as better value for money than bus rapid transit (Hensher, 1999). In terms of rail, light rail is usually a cheaper alternative to heavier rail modes such as suburban and commuter railways and (underground) metros, quicker to implement than heavy rail, and while light rail may share road space with other vehicles, stations, stops and services are more frequent in the city center, thus providing a fast and accessible service. Table 1 provides a summary of light rail characteristics.

Geographically, light rail investment has spread to cities across the globe since its 1970s renaissance (see below). UITP, the International Association of Public Transport, identified 411 cities with light rail in 2018 though this is not definitive given the broad definition of light rail (UITP 2019). Europe and North America are regarded as traditional regions of light rail development and Europe records the highest number of cities featuring light rail (see Fig. 3). As shown in Fig. 4, Asia-Pacific was identified as the leading region for light rail development in 2017 and 2018 (as measured in kilometers (km) of track) with 110.3 km constructed in 2018. Light rail in the Middle East and North Africa (MENA) is also growing rapidly (and ahead of North America). In Europe and North America, while light rail investment continues, it tends to be more focused on maintaining and replacing existing infrastructure rather than new developments. The expansion of light rail investment—new development, extension of lines, or conversions to light rail—has been boosted by its implementation in medium-sized cities (100,000–300,000 inhabitants) as well as larger conurbations. Not all countries that invested in light rail have continued to develop their systems. Some older systems have been closed during this period and some countries, including the UK and the Netherlands, have slowed investment.

Light rail investment has become popular in the wake of concerns over urban traffic congestion and has become part of broader sustainable mobility and sustainable urban agendas (see below). In addition, it is widely recognized that light rail can act as a catalyst or enhancer of urban (re)development and investment that can help to boost a city or region's economic growth and raise its competitive standing. Light rail literature, which includes academic work from the social sciences, engineering, environmental science and urban planning, as well as a range of professional impact studies and reports, provides substantial insight to ex ante and ex post assessments of light rail. This literature tends to adhere to neoliberal urbanism, competitive urbanism and, more recently, sustainable urbanism, leaving a significant gap on more environmental, social and humanistic approaches to light rail.

History

The origins of light rail are typically grounded in the development of streetcars in North America and Europe during the nineteenth century (in New York City 1832, Paris 1855, London 1861, Copenhagen 1863). In France, tram routes totaled more than 3400 km in length in their heyday during the early 20th century (Bouquet, 2017) and 55,150 streetcars were listed in the inventory operated by North American transit companies in 1930 (Culver, 2017). These early streetcars enabled city residents to move out of the center and live in the suburbs as well as opening new land for development outside of the city and providing vital connections between places. However, streetcars declined through the 1920–1960s as the burden of maintaining and replacing rail track contributed to a rise in bus services as a key means of public transport, while the rise of automobile sales, particularly post World War II, further diminished

Table 1 Common characteristics of light rail.

Running ways	Exclusive rail transit-ways, surface, underground or overhead; maximum gradients 8%–10%; priority signaling where rails cross/share road space.
Stations/stops	Large stations with security and passenger information systems; sometimes transit interchanges; sometimes space for cafes and shops; park-and-ride facilities. Medium distance between stops 250–1200 m.
Service design	Frequent services (max. 40–60 trains/h); often integrated with other transport services; high capacity (8000–15,000 passengers/h); average speed 20–40 km/h.
Fare collection	Off-board prepayment; smart/travel cards.
Additional features	Passenger information systems; multi-door and level-boarding; branding; modern design.

the need for and provision of streetcars. With urban investment directed towards the automobile and buses, many streetcar lines were abandoned. By 1960, only 15 systems continued to operate in France, while in North America the number of streetcars had declined to 2856. Germany is often given as an example where streetcar infrastructure continued.

Renaissance

The term “light rail” emerged with a renaissance of streetcars in North America and European countries in the 1970s. Employed in 1972 by the US Mass Transportation Administration (now the US Federal Transit Administration (FTA)) to describe streetcar transformations, light rail was more formally defined in 1989 in the Transportation Research Board’s Urban Public Transportation Glossary. By that time, the well known pioneers of the streetcar renaissance—Edmonton, Canada, 1978; San Diego, US, 1981, Nantes and Grenoble, France, 1985 and 1987 respectively—had been joined by other cities, and investment in light rail was growing quickly (UITP, 2015). Reinvestment in this renaissance was largely a response to concerns over urban traffic congestion and pressures for policy-makers to invest in new and improved public transport for environmental reasons. Light rail became popular; however, it is recognized as more than just a transport mode and its potential to accompany or facilitate urban

Figure 4 Evolution of LRT development by regions (km). Source: UITP 2019. Reproduced with permission.

development has made it very attractive for cities pursuing economic growth. This economic logic is a key reason for investment alongside improving public transport and alleviating traffic congestion.

The Promise of Light Rail

Light rail's potential and actual impacts are key concerns for professionals and academics. Commonly expressed as direct impacts or user benefits on the one hand, and indirect impacts or non-user benefits on the other, assessments of what light rail could and has achieved form important assessment criteria in the planning, decision-making, and evaluation of light rail investment.

User Benefits

Direct benefits acknowledge that light rail usually provides an attractive high-capacity and high-quality service to and through the city center in terms of frequency, speed, and reliability, particularly at peak hours (Bhattacharjee and Goetz, 2012; McAslan, 2019). Light rail can improve accessibility through new connections and reduced journey times. Light rail can also increase use of public transport (via newly generated trips as well as capture of users from other modes) though not all cities report this success (Engerbretsen et al., 2017; Senior 2009). Common performance measures include farebox revenues, journey times and reliability, ridership and travel behavior including individuals' access to light rail stops and stations, and modal shift of passengers, particularly from cars (Ingvardson and Nielsen, 2018). Some researchers have found that light rail can help to bring about modal shift with positive evidence from light rail lines in Nantes (17%–37%), San Diego (30%–50%) (Lee and Senior, 2013), and Manchester (21%) (Knowles, 1996). Other researchers find that modal shift has not occurred (Olesen, 2014).

Multimodal transport integration is another user benefit where light rail provides trunk and feeder services to help provide a seamless journey that includes first- and last-mile interconnections. Research has shown that other transit modes (e.g., buses, cars and bike-sharing) can be integrated effectively but there is also evidence that alternative modes act as competitors, particularly where they are in direct competition for fare revenues (Lee et al., 2017) (see Table 2).

Light rail user benefits also contribute to the perception of light rail as a sustainable transport mode (see below).

Non-User Benefits

Non-user benefits of light rail follow the broader classification of economic, environmental or social impacts though studies of economic impacts (wider economic impacts (WEIs)) significantly outnumber those analyzing environmental and social impacts and most focus on light rail's impact on development (land-use) and land and property values. Studies are based on the premise that transport facilitates the shape and extent of urban development and can lead to increased land values around stations and stops. A seminal report by Knowles and Ferbrache (2014) on the economic impacts on cities of investment in light rail provides a synthesized review of academic and non-academic literature and recommendations for boosting light rail's wider economic potential. Findings demonstrate that light rail can facilitate and enhance urban development through stimulating new growth, regeneration and redevelopment, and city center revitalization and boosterism as explained below.

Table 2 Strengths and limitations of light rail success in seven cities.

	<i>Strengths</i>	<i>Limitations</i>
St Louis Metrolink, US	Location of line and stations Provision of access over the river Integration with bus services Free city center journeys (off-peak) Security staff on board and at stations Provision of car parks at station sites	Weak and declining CBD Lack of comprehensive redevelopment project Over-allocation of station area space for car parks
San Diego Trolley, US	Location of the initial line Integration with bus services City center development project Other joint development projects Transit oriented development schemes	Weak integration of local plans with the trolley in some municipalities
Sacramento Light Rail, US	Strong and economically vital CBD Integration with bus services including free transfers between systems Pedestrianization of a city center street	Inconvenient and low density urban form Inconvenient route selection High income neighborhoods contra TOD Lack of funds to improve buses Poor service levels (low frequency) Provision of only one park and ride facility
Vancouver SkyTrain, Canada	Medium-high density urban area Substantial levels of public transport usage High frequency service Integration with bus services Integration with regional and local plans Redevelopment of old industrial sites Development bonuses (TOD incentives) Joint development schemes Relocation of government buildings to stations Early opening of a section for demonstration	
Tyne and Wear Metro, UK	High density urban area with radial corridors Substantial levels of public transport usage Location and length of lines Part of a city center redevelopment project Integration with bus services initially	Over time, lack of integration with buses Poor co-ordination with local plans and more recent urban projects
Manchester Metrolink, UK	High density urban area with radial corridors Substantial levels of public transport usage Provision of access through the city center High frequency Location of lines: replacing rail commuter service and providing city center rail link Renewal of some city center buildings Pedestrianization of a city center street	Lack of integration with bus services Poor integration with local municipal plans
Sheffield Supertram, UK	Medium density urban area with radial corridors Substantial levels of public transport usage Ticket sales on board Signaling priority improvement	Small and weak CBD System serving low income neighborhoods combined with competition from buses Low segregation and low signaling priority Demolition of high density residential areas Poor co-ordination with urban renewal project

Light Rail and Urban Development

Light rail can help to stimulate new investment by raising the appeal and attractiveness of city locations as well as providing access to new sites. It was widely reported that the relocation of many of the British Broadcasting Corporation's (BBC) activities from London to the MediaCityUK development at Salford Quays rested on a £20 million public sector investment in an extension of the Manchester Metro link to MediaCityUK (Knowles and Binder, 2017). Several methodological caveats accompany evidence of new economic investment and some of the other potential benefits of light rail including: (1) linking specific economic investments solely to light rail remains problematic for it does not operate in isolation; (2) analytical scale is important for new investment may be based on relocation and thus investment decline elsewhere.

Light rail can facilitate and enhance urban regeneration and redevelopment including former derelict docklands (for example the London Docklands, UK), brownfield sites and industrial areas (e.g., Sunderland, UK). In this respect, light rail can open access to areas previously difficult to reach. Land was unlocked in this way in Copenhagen where Ørestad New Town (mixed-use

Figure 5 The pedestrianized and landscaped Place Garibaldi, Nice, France. Source: Myrabella/Wikimedia Commons/CC BY-SA 3.0 & GFDL.

development for educational, leisure, office, residential and retail use) was built around Copenhagen's new light rail mini Metro system on reclaimed land (Knowles, 2012).

Light rail has also been a catalyst for revitalization, notably in terms of car-oriented city centers transformed into public transit hubs with pedestrianized areas and landscaping to help stimulate interest and investment in the heart of the city (see Fig. 5). Grenoble is a leading example of this transformation and has become a model for other cities to follow under the popular label "the Grenoble effect." Revitalization effects have also been captured through the term "city boosterism" that reflects a competitive urbanism where light rail is used to boost a city's image (Ferbrache and Knowles, 2017). Through branding light rail vehicles (the 'M' logo of Newcastle and Tyne's Metro has become an emblem of the city), creating iconic infrastructure (such as light rail stations, bridges, tunnels, and grassed tracks), and designing light rail as an integral part of the city (trams in the French port city of Marseille are designed to look like the bow of a vessel, while burgundy-colored trams in Dijon are designed to represent the wider region's wine heritage), both the transit infrastructure and the city can become symbols of urban modernity. Other authors have expressed such design features in terms of place-making (Ferbrache and Knowles, 2017; Olesen, 2014; Olesen and Lassen, 2016).

Land and Property Values

By improving accessibility, light rail usually increases land and property values close to stations and stops. For example, the DLR triggered an increase in accessibility and land values in the Isle of Dogs, rising from £70,000 an acre in 1981 to £4.9 million an acre in 1988. A relatively significant number of studies examine light rail impacts on property values for residential and commercial buildings (see reviews in Knowles and Ferbrache, 2015; Ingvardson and Nielsen, 2018; Mohammad et al., 2013; Song et al., 2019) and while results vary, they tend to demonstrate an upward trend. Property and land premiums are usually expressed as positives under a neoliberal framework where they are valued for boosting economies or as potential mechanisms to help fund the very infrastructure that lies behind their value-rise. In this way, land and property value increases can be captured and reinvested although this is not always the case in practice (Cervero and Murakami 2009; Knowles and Ferbrache, 2014). Ørestad Metro in Copenhagen is one example that was partly funded by sale of public land at enhanced values to private developers. Reflecting a primary economic stance, and one which celebrates the benefits of light rail, analysis of property prices often neglects issues of displacement and gentrification (Bardaka et al., 2018).

While the above categories are not exclusive (new investment may be an essential part of redevelopment), they indicate significant ways that light rail has been valued. Given the number of light rail systems operating, available evidence and robust studies are relatively thin. Most literature examining economic impacts aim to tell success stories, suggesting that negative impacts may be overlooked or under-reported. There are also methodological issues involved with identifying potential impacts and a risk of assuming that light rail impacts can be isolated from other influential factors. Cervero (1984:146), for example, states that "For LRT to have an extensive impact on urban form, a strong and growing regional economy is an important prerequisite." Furthermore, light rail requires heavy capital investment, political and public commitment, and some systems are implemented cheaply and without adequate planning to bring about their potential benefits when tailored to the needs and design of specific cities. Table 2 provides examples of factors that determined the strengths and limitations of different light rail systems and this type of analysis is another important area of light rail research (Babalik-Sutcliffe, 2002; Mackett and Edwards, 1998; Mackett and Sutcliffe, 2003). Common within the literature is the argument that the most successful light rail schemes are those that are integrated with urban planning initiatives, particularly with transit oriented development (TOD) (Arrington 2009; Goetz 2019; Lavery and Kanaroglou, 2012).

Sustainability

Light rail is valued in terms of sustainability and "smart growth" strategies with emphasis on sustainable transport and mobility (infrastructural efficiency and resilience), sustainable (urban/economic) growth and environmental sustainability. Sustainability in terms of social equity has been largely neglected in comparison (Ferbrache and Knowles, 2016).

From an environmental perspective, light rail is electrically powered and therefore relatively low energy compared to other transit modes. It is expected to support reductions in energy use, noise and air pollution, including carbon emissions. However, while Park

and Sener (2019) observed lower levels of carbon monoxide and other emissions in Houston, US, little empirical evidence currently exists on air quality effects of light rail (FTA, 2016).

As a sustainable transport mode light rail can move relatively high passenger capacities at higher speeds in city center locations and its very characteristics and user-benefits enhance its reputation as one of the leading sustainable modes. Moreover, light rail is the transit mode at the center of many TOD projects which combine transport investment and urban planning to create resilient cities into the future (Arrington, 2009; Goetz, 2019; Knowles and Ferbrache, 2019). While TOD has often been justified in terms of economic growth potential, a more critical approach that pays attention to social mobility and liveability in this urban-transport development context holds potential for drawing attention to the possible social impacts of light rail.

An emergent area of research and practice, Mobility-as-a-Service (MaaS) has important implications for light rail in terms of enhancing passenger information systems, fare/payment systems, and multi-modal integration, including innovative modes such as aerial cableways and autonomous vehicles (Knowles et al., 2020). Research around this concept has the potential to stimulate further interest in light rail among researchers, and help to improve the efficiency, usability and sustainability of light rail going forward.

Social Exclusion and Gentrification

Grengs' (2005) claim that planners have lost sight of potential social benefits of mass transit resonates with literature and experience of light rail (Cuthill et al., 2016; Jones and Lee, 2016). Few studies have considered the social, health and wellbeing impacts of light rail. Exceptions include Farmer (2011) who demonstrated how light rail contributed to fragmentation and exacerbation of social divisions in Los Angeles. Nilsson and Delmelle (2018) found that impoverished neighborhoods were more likely to experience gentrification with transit station opening. Other researchers demonstrate light rail's socioeconomic achievements: Sari (2015) demonstrates that Bordeaux's tram has helped to reduce socio-economic inequalities through improving access to jobs. Cuthill et al. (2019) found that Croydon's Tramlink has also been able to help alleviate some social equity issues, particularly for young people. Adopting a different approach, Nolte and Yacobi (2015) demonstrate the powerful representations of light rail promoted in Jerusalem to unite divided Israeli and Palestinian populations. Such studies bring an important humanistic perspective to light rail that connects it with literature examining quality of life, liveability and the creation of healthier cities (Appleyard et al. 2019; Diemer et al. 2018), while at the same broadening what it means for light rail to be sustainable. A potential gap remains, however, between research of this nature and practical approaches to light rail planning and investment, which remain largely reliant on cost benefit analyses. In this way, the economic case for light rail remains pivotal in decision-making (Knowles and Ferbrache, 2014).

Traditional Planning Model for Tourism Travel

Every tourism experience can analytically be segmented into its five component phases (anticipation, outward journey, experience phase, return journey, and memory). The planning of tourism travel represents the main activity that characterizes the anticipation phase. A model proposed by [Bansal and Eiselt \(2004\)](#) considers travel planning as the interaction of motivations and constraints that leads first to the selection of a determined region and consequently to the transport means, accommodation, and all other complementary goods and services that compose the tourism experience.

Several studies have tried to analyze the motivations that may lead a tourist to plan a determined holiday or vacation (for a review, see [Yousaf et al., 2018](#)). A seminal paper by [Maslow \(1943\)](#) has proposed a general motivation theory based on five levels of needs. The first level is constituted by physiological needs (e.g., food, warm, and rest) that in the case of tourism determine the basic expectations of people traveling toward a determined destination. The second level is related to safety and security needs. It is evident that countries or destinations which do not offer adequate levels of security will experience drastic decreases in tourist demand, unless they propose some *enclaves* with physical and technological barriers between visitors and residents. These first two levels constitute the basic needs that destinations have to supply in order to be the possible target of any tourism travel planning. The third level attains the belongingness and love needs (as intimate relationships and friendships). In the case of tourism travel, this relates to the attitude, especially of neophilic tourists, to try and become familiar with the local communities of the regions that they visit. This specific need determines also the cultural tourism demand where the main aim of the travel is the desire to acquire knowledge about other cultures and countries. The fourth level relates to esteem needs. In the case of tourism, travel is performed in order to impress the group of peers or family and friends. Lastly, the fifth need is the feeling to have accomplished one's objectives (self-actualization or achieving one's potential, by also engaging in creative activities and performances). This motivates some tourists to travel to challenging destinations and to perform demanding activities. Two variants of Maslow's theory have been presented by [Pearce \(1988\)](#) and by [Pearce and Lee \(2005\)](#), listing all possible motivational factors that drive tourist travel planning.

A different theory was presented by [Dann \(1997\)](#) who made a division between push factors that are internal to the tourist and are related to the need to rest and escape from the everyday setting and pull factors that emerge from destinations, which present a series of attractions, amenities, activities, and ancillary services that motivate the tourists toward them.

Several authors have proposed a taxonomy of possible constraints to tourism travel planning (see, among others, [Nyaupane and Andereck, 2008](#)). It is possible to consider three possible categories of constraints: intrapersonal, interpersonal, and structural constraints. Intrapersonal constraints are related to the psychological conditions of individuals, which may change even in very short periods of time and that may lead to the willingness to avoid the participation to a travel activity. Possible examples are represented by anxiety, depression, lack of interest, or stress. Interpersonal constraints consider the situations in which an individual is part of a traveling group (family, friends, or colleagues), and consequently all travel decisions must be bargained within the group with the result that individual preferences are only very seldom met. In other cases, it may happen that a potential traveler is not able to find a traveling companion or group for her desired tourism experience. Lastly, structural constraints refer to all the external factors that are interposed between preferences and participation to a travel. The most cited examples of external constraints are the scarcity of time and money. However, many others should be considered such as adverse weather conditions (which determines a remarkable seasonality of demand for many tourism destinations), the lack of effective marketing of some countries or regions, and the low degree of accessibility that in some cases is due to the inefficient transport services and planning.

The Role of Transport in Planning Tourism Travel

One of the most important drivers of the evolution of tourism activities in the past decades is represented by the increased availability and affordability of transport services (see, among others, [Schiefelbusch et al., 2007](#)). This has led to a marked upward trend in

tourism travel, both in terms of volumes and distances. As an example, international tourists have passed from 25 million in 1950 to 1.4 billion in 2018. The drastic increases in tourism travel and mobility have determined momentous consequences for the natural and human environments where the transit regions have borne the burden of transport externalities without any sensible economic advantage. It would then be important to plan tourism travel by taking into consideration all possible measures that may lead to sustainable management of transport activities. Such measures would likely fall in one or more of the following six categories: alternative fuels/energy sources, improved energy efficiency and technology, investments in infrastructure, operational measures, behavioral measures, and taxes and subsidies (Peeters et al., 2019). However, sustainable transport measures should also take into account the effects of a reduction in the number of trips, given that tourism represents an important source of revenues, jobs, and gross domestic product growth. More sustainable tourism travel (which may imply slower journeys and longer periods of staying once at destination) may be feasible only for a limited, privileged, share of citizens. Most of the population may deem these sustainable tourism travel activities either as undesirable or unaffordable in terms of time and/or of economic budget. It is then evident that the development of tourism travel depends on the degree of accessibility of a determined area and of the planning activities that have been undertaken to increase it. Litman (2008) has proposed a taxonomy of all the factors that affect accessibility and, in the case of tourism, determine the likelihood of people to choose a determined destination in their planning activities. The next subsection will offer a general description of each of these factors and will then contextualize them to the case of tourism travel planning.

Factors Affecting Accessibility and Planning in Tourism Travel

The following is a description of the factors affecting accessibility and that are of paramount importance when planning tourism travel. One of the factors considered in Litman's taxonomy, mobility substitutes or the telecommunications and mobility services that substitute for physical travel, will not be considered given the lack of relevance in tourism travel. The general descriptions will be based on Litman (2008), while the discussions of their relevance for tourism travel are the author's elaborations.

- *Transport demand* refers to the amount of mobility and access that people would choose. In the case of tourism travel, it considers the amount of tourism demand for a determined destination. For the large majority of destinations, it is important to consider the seasonal pattern of demand, characterized by peak periods, shoulder periods, and low demand periods. For planning purposes, it is important to forecast tourism demand. This can be accomplished by using time series analysis, autoregressive moving average methods, support vector machines, or neural networks models.
- *Mobility* considers the travel speed and the distance to be covered. In general transport literature, this topic has been considered as travel time and travel reliability. In the case of tourism travel, this issue has two possible meanings. On the one hand, it may be related to the amount of time that is necessary to reach the desired tourism destination (mobility toward tourism destinations). On the other hand, it may be directed at accounting for the amount of time required to move within the destination in order to perform the activities that characterize a tourism experience.
- *Transport options (modes)* indicates the quality of the various transport options, including walking, cycling, public transport, and private motorized transport modes. In the case of tourism travel, the availability of various transport modes has to be carefully considered given that at the tourism destinations there may be options that are not normally part of the possible choice set in everyday life. Moreover, during holiday periods, the amount of discretionary travel increases substantially with respect to required or forced travel activities.
- *User information* represents the availability of reliable information on mobility and accessibility options. The availability of information is a particularly important topic to consider when analyzing the planning of tourism travel. In this context, both information and communication technologies (ICT) and smart technologies and social networks have assumed pivotal roles. Their relevance will constitute the object of the analysis in the following section "The Current Trends in Planning Tourism Travel."
- *Integration* denotes the degree of connectivity among transport system links and nodes. In the case of tourism travel, it is very important to create an integrated transport system that allows for tourists to reach their desired destination in a reasonable amount of overall traveling time. This is because the travel from the place of residence to destination requires the use of multiple transport modes (e.g., plane and bus, plane and train, and so on), unless people decide to travel with their own private motorized vehicle. In this context, the coordination and the partnerships between private stakeholders and public administrations can determine positive synergies and enhance the degree of integration among transport modes.
- *Affordability* refers to the cost of mobility for individuals as a share of their relative incomes. This increased economic affordability has most probably been the main determinant to move tourism from a luxury activity available only for a very limited share of the overall population to a possibility for the vast majority of people in developed countries with the ensuing development of mass tourism travels.
- *Land use factors* consider how land use density and mix affect travel distances and costs. Within tourism, the land use affects the degree of satisfaction of tourists once they are at destination. Moreover, it is an important element of the relationships between tourists and residents. In some cases, these two categories share the same places, with the emerging positive and negative externalities. In other destinations, according to the social exchange theory, land use planning determines a clear distinction between the areas where tourists interact with each other and the zones where residents go to in order to avoid tourists.
- *Transport network connectivity* concerns the density of roads and path connections and then the directness of travel between destinations. This is an issue where tourism travel is only part of a more general planning activity by the public administrations

that need to take into account the needs and requirements of a large number of stakeholders. This is a long-term concern where it is possible to observe a remarkable path dependency. In the case of tourism, accurate investments may favor the growth of complementary forms of tourism with sensible externalities for all the interested adjoining areas.

- *Transport management* designates how the rules and regulations issued at the various administrative levels impact on the accessibility of a determined destination. This is a complementary issue with respect to land use factors and transport network connectivity. An appropriate transport management ensures that the most efficient (and possibly environmentally and socially sustainable) alternative is available for tourists at the right place and at the right time. Tourist transport management is, in general, connected to public administration activities, but it can also stem from private initiative.
- *Prioritization* implies strategies that favor more efficient travel activities. This constitutes an important element in the overall tourism development strategies, given that the prioritization of specific infrastructures and services can determine the development path of the tourism phenomenon in a destination.
- *Inaccessibility* denotes the value of inaccessibility and isolation, which in some cases requires to limit the access possibilities. For some niches of the tourism travel, such as adventures and elite forms of tourism, the inaccessibility is considered as a positive asset. In all other cases, the degree of inaccessibility should be reduced as much as possible so that the destination can increase its market share and the satisfaction of tourists.

A review proposed by [Van Truong and Shimizu \(2017\)](#) has ascertained that, despite the relevance of all these factors for the development of tourism travel, very few studies have taken them into consideration when estimating the effect of transport on tourism travel. Some studies have considered infrastructure improvements, information provision, and travel costs while most of the others described factors have been neglected and would deserve to be included in the analysis of tourism travel planning.

The Current Trends in Planning Tourism Travel

The passage of most of the goods and services that compose the tourism activities from experience goods to search goods is one of the most relevant methodological shifts that have characterized the tourist sector in the past decades. An experience good is a consumption good (or service) whose quality and peculiar characteristics can only be asserted by the tourist only after its consumption. On the other hand, a search good is a consumption good (or service) whose quality and peculiar characteristics can be asserted by the tourist before its purchase and consumption. This shift has momentous consequences on the planning of tourist travel. Two of the most important determinants of this trend are represented by the diffusion of ICT and by the increased relevance of social networks and user-generated content, originating from the use of these new technologies. The following two subsections will present a discussion of these two factors, emphasizing their role in the planning activities of tourists.

The Role of ICT for Tourism Travel Planning

A study by [Money and Crofts \(2003\)](#) has stated the principle that the amount of activities devoted to the acquisition of information is limited to the point in which, coherently with general economic theory, the marginal benefit of a further act of search is higher than the marginal cost. Moreover, search is partitioned in internal search (which identifies the retrieval of previously acquired information) and in external search. In the latter case, the sources of information can either be: (1) personal (e.g., previous experiences of friends and relatives), (2) marketing or advertisements, (3) neutral by third parties who are not directly interested in the act of purchase (see section “The Relevance of Social Networks and User-Generated Content for Tourism Travel Planning”), or (4) experiential through direct contacts with the retailer. Important sources of external search that may in some cases be linked to marketing and advertisement practices and in others to the neutral information sources and that have taken a leading role in tourism travel planning are the ICT and the smart technologies ([Steen Jacobsen and Munar, 2012](#)). Their main benefit for the tourist who has to plan the travel is represented by the reduction of search costs and the consequent possibility to perform a larger number of searches in a determined period of time. Moreover, they allow the option to double-check the information obtained through traditional channels, such as travel agents and guidebooks. [Xiang et al. \(2015\)](#) have characterized the use of ICTs for travel planning as an adaptive behavior that tries to take advantage of the new opportunities provided by these new search tools. They have then identified various trends that have emerged from the use of ICTs for travel planning. The first one considers that the use of ICTs for travel planning is saturated and represents the main source of information. Within all products that compose the tourism experience, ICTs are particularly used for the choice and purchase of travel tickets, accommodation, and car rental. The problems that had marked the early phases of ICT adoption for tourism travel planning (e.g., poor usability and lack of personalized services) appear to have been overcome by their evolution. The second trend is related to the use of ICT for planning purposes by all age cohorts, although the younger ones appear to be more engaged, and to choose from a wider range of options. A further trend is constituted by the adoption of ICT tools also for the search and purchase of secondary products (e.g., museum tickets and tourism shopping). [Derrick Huang et al. \(2017\)](#) have clarified that the main attributes of ICT for travel planning are informativeness (quality and trust of information), accessibility (easiness to access appropriate information), interactivity (real time feedbacks and active communications), and personalization (possibility to obtain information that is coherent with personal travel planning needs). They then conclude that the use of ICT allows to consider a much wider range of alternatives and to enhance the satisfaction of tourists. The issue of tourists’ satisfaction linked to the use of ICTs has also been carried out by [Woo Yoo et al. \(2017\)](#). They conclude that the level

of satisfaction and the quality of information obtained by using ICTs for travel planning is positively correlated with the skills and confidence of ICTs possessed by the tourist who use them.

The Relevance of Social Networks and User-Generated Content for Tourism Travel Planning

The transformation of the informal word of mouth channels to retrieve efficient information for the tourism travel planning to a formal set of websites, apps, and social networks has been one of the effects of the widespread use of Internet (Cox et al., 2009). One of the main issues originating from the diffusion of this new tool to acquire information was related to the degree of trustworthiness that the provided information may have. This is evident for both consumers and suppliers of tourism goods and services. The latter must take into account the increasing popularity of these new planning tools and must consequently monitor the information provided about their firms, services, and establishments. A study by Fotis et al. (2012) has shown that social media are used throughout the entire process of travel planning and that their influence is higher on the destination and accommodation choices. The degree of trustworthiness is second only to the information gathered through friends and relatives. Lastly, it appears evident that there is a high rate of heterogeneity depending on the various considered national markets. Another source of heterogeneity has been proposed by Simms (2012) who has highlighted that some of the trip characteristics (i.e., location of the destination, familiarity with the destination, and travel party composition) influence the engagement of tourists in user-generated content for travel planning. Ayeh et al. (2013) have suggested that ease of use, perceived enjoyment, and positive attitude play an important role in the use of social media and user-generated content for travel planning. On the other hand, complexity and the perceived effort have negative effects on the likelihood of travel information searches through social media (Chung and Koo, 2015). A last important factor is represented by the perceived similarity of interests between the generator and the user of relevant information. A general theory has been proposed by Mendes-Filho et al. (2018) by jointly taking into account psychological empowerment and technology acceptance. The former considers the capacity of people to develop efficient decision making and the discretion to carry out a specific behavior. The latter comprises perceived usefulness and ease of use of the technological tools.

A different tourism travel planning issue has been studied by Cenamor et al. (2017) who have proposed a possible tourism tool that mediates between social networks and smart travel technologies. The system would create personalized excursions and tourism routes, based on a series of parameters introduced by the tourist (e.g., length of stay and specific cultural interests), by using the consumer-generated information gathered in a traveling social network. This interaction of technology and social networks may represent an important evolution that may greatly enhance the tourism travel planning options based on the specific preferences of the individuals.

Conclusions

The article has shown that tourism travel planning is based on the interactions between motivations and constraints, which lead to the selection of a determined destination and of the activities to perform once it is reached. Motivations may be categorized either as a multilayered series of needs or as the interaction of push and pull factors. On the other hand, constraints can either be intrapersonal, interpersonal, or structural. Within the latter category, transport constitutes a pivotal element in planning tourism travel. The past decades have been characterized by a remarkable increase in the availability and affordability of transport services that have allowed a wide diffusion of tourism activities and that have called for an effort to enhance the share of sustainable tourism travel activities. A related important issue is the degree of accessibility of tourist regions, in terms of travel both toward and within the destination. All factors affecting accessibility (transport demand, mobility, transport options, user information, integration, affordability, land use, transport network connectivity, transport management, prioritization, and inaccessibility) represent topic elements in tourism travel planning for both private actors and public administrations. They are particularly important elements to consider in periods marked by disruptive events, such as the COVID-19 pandemic whose effects on transport and tourism have started to be manifest in 2020. In this context, ICTs, social networks, user-generated content, and their interactions may demonstrate to be more and more essential, given the degree of informativeness and of interactivity that they allow to achieve. Moreover, they permit to reduce the search costs for the best possible alternative, and they are characterized by a high degree of trustworthiness among users. All the aforementioned factors of accessibility would deserve to be jointly considered in the future analyses of tourism travel planning in order to propose robust models and sound evaluations of current practices and activities.

Introduction

In general, transport planning over the past 50 years has lacked a clear theoretical foundation ([Banister, 2002](#)). Transport-related problems, such as climate change, air pollution, energy consumption, traffic congestion, accidents and safety issues, and transport inequalities have become apparent due to the increased demand for unsustainable transport and inefficient transport planning and management, particularly in most developing countries. As a growing number of people are living in urban areas, one of the key factors in terms of creating successful and sustainable cities involves developing a sustainable transport system which is able to meet the needs of rapid economic growth, as well as caring for the environment, and improving the quality of people's lives ([Attard and Shiftan, 2015](#); [Hickman and Banister, 2014](#)). As the world's largest developing country, China has been significantly affected by the aforementioned issues. This chapter aims to enrich our general understanding of the status quo and the current strategies that have been implemented in terms of transport planning and management in Chinese cities, as well as offering new insights into the debate about how to improve transport users' perceptions, an aspect which has long been overlooked.

The next section describes the history of transport development in China, while the third section provides an overview of the status quo regarding transport planning and management issues, as well as critically discussing some of the strategies that have been implemented, and their implications for Chinese cities. The conclusion summarizes the key findings and contributions, as well as offering reflections.

The History of Transport Development in China

Since the Chinese revolution of 1949, and particularly since the reform and opening up policy, instigated by Xiaoping Deng, was introduced in December 1978, transport has undergone historic changes, which have made a significant difference to people's lives in terms of economic and social development, travel safety and increased mobility. Since the beginning of the 21st century, the Chinese government has comprehensively extended the reform of transport, accelerated the construction of a modern and comprehensive transport system, and continuously promoted the modernization of the governance system and governance capacity of the transport industry.

In the mid-twentieth century, the development of the Chinese transport system lagged far behind that of the rest of the world. For example, the total mileage covered by the national railway amounted to only 21,800 km, half of which was virtually unusable. Furthermore, there were only 80,800 km of roads and 51,000 private vehicles in the country at that time. Inland waterways were in need of improvement, while a mere 12 civil aviation lines served the whole country. There were fewer postal service points due to the poor quality of freight transport. The main means of transport were rickshaws and wooden sailboats ([State Council Information Office, 2016](#)).

Since 1953, the construction of transport infrastructure has been carried out in a planned manner. In 1956, the General Administration of Highways, a department of the Ministry of Communications, appointed experts to study the first draft of highway planning in China. During the first and second 5-year plans and the adjustment of the national economy from 1953 to 1965, the state started investing in the transport infrastructure, renovating it and building a number of railways, roads, ports and civil airports, thus increasing the coverage of the transport infrastructure in western China and remote areas. Dredging of the main waterways also took place, as well as the opening up of new international and domestic waterways and air routes, expansion of the postal network, and a substantial increase in the amount of transport equipment. During the Cultural Revolution (The Cultural Revolution was a

socio-political movement in China) between 1966 and 1976, the development of transport was significantly disrupted, but the scale of facilities, equipment and transport lines was still increased overall (ibid.).

In 1978 the Chinese economic reform (known as the “Opening of China”) heralded a new chapter, particularly in terms of economic and social development. During this period, the Chinese government prioritized the development of transport, strengthened policy support, undertook groundbreaking work in liberalizing the transport market and established socialized financing mechanisms. In 1982, it was pointed out that, “if people want to be rich, they need to build the road first.” This was first done in Meishan county, in Sichuan Province, and then across the whole of China. In 2007, the China railway speed-up campaign was implemented in six rounds. Comprehensive highway and water transport planning was carried out in relation to the main skeleton of the road network, the key water transport routes, and the main ports and station hubs and their support systems. In 2008, the Ministry of Transport was set up, and substantive steps were taken toward reforming the system of transport departments. In the same year, the Beijing–Tianjin inter-city railway became fully operational, and China entered the “era of high-speed rail” (ibid.).

In 2013, the construction of comprehensive transport, intelligent transport, green transport, and safe transport were put forward as key themes to inform the development plans for the construction of the Belt and Road Initiative (The Belt and Road Initiative (also known as One Belt One Road) is a global development strategy implemented by the Chinese central government involving infrastructure development and investment in the Americas, Middle East, Africa, Europe and Asia), the coordinated development of Beijing, Tianjin, and Hebei (Jing-Jin-Ji project), and the construction of the Yangtze River economic belt (ibid.).

Over the past few years, with China’s rapid urbanization (Guan et al., 2018; Wu and Ma, 2006), expanding the public transport network and improving its efficiency have become the main priority for Chinese cities (General Office of the State Council, 2018). The following section discusses the current situation and some of the main strategies used in relation to transport planning and management in China.

Current Transport Planning and Management Problems and Strategies

Current Situation

At present, transport-related economic (cost–benefit analysis and/or wider impacts of transport investment) and environmental (low-carbon transport and/or green transport) concerns are a priority for transport planning and management in China (Cao et al., 2017; Guo and Meng, 2019; He et al., 2019; Loo, 2018; Wang et al., 2015). There has also been a growing awareness of the importance of other pillars, such as transport-related social impacts (Attard, 2020; Cao and Hickman, 2019b, 2020; Li and Zhao, 2018; Zhao and Bai, 2019). In other words, boosting local and regional economic development remains the key aim for most Chinese cities, as well as accommodating the rapid growth in private vehicles, particularly in some of the megacities, where the transport system is overcrowded but public transport services remain limited. In addition, similarly to other cities around the world, increased car usage and urban traffic congestion, especially in tier 1 and tier 2 cities (e.g., Beijing – Tier 1 city; Xi’an – Tier 2 city), present problems that are becoming increasingly difficult to resolve in relation to urban development and operation (Li et al., 2019). Consequently, people have to allow a lot of time for their commuting (Zhu et al., 2017). Although transport planners and policymakers recognize that reducing the heavy congestion, and shifting away from extending roads and overpasses to prioritizing the development of public transport within Chinese cities is paramount (State Council, 2012), there are still a number of issues that need addressing. Three key points, namely the quality and demand/supply capacity of the public transport system; transport pricing; and traffic rules, are discussed below.

First, the quality and adequacy of the existing public transport system have not met most transport users’ expectations or kept pace with demand. For instance, Wu et al. (2019) pointed out that, apart from commuters who use the shuttle bus, statistics have shown that few people felt significantly greater satisfaction with commuting by public transport than by private car. If public transport fails to offer any potential benefits and/or greater satisfaction, it is difficult to persuade private car users to switch from their current travel mode to using public transport. Furthermore, an increase in commuting has caused the public transport network to become increasingly overloaded, particularly at peak times due to the limited capacity on buses and on the underground. Therefore, in order to avoid using crowded and uncomfortable modes of public transport, many people choose to commute by private vehicles, as their non-instrumental—symbolic and affective—motives may not be fulfilled by public transport (Steg, 2005). People perceive that car ownership can improve their travel satisfaction and enhance the quality of life (Gärling and Schuitema, 2007), in a way that public transport, in its current state, cannot. Thus, transport planners and policymakers should also consider improving the quality (e.g., providing Wi-Fi, air-conditioning, and women-only carriages) and capacity of public transport rather than focusing solely on increasing its speed and extending the transport network.

Furthermore, public transport pricing is one of the most important factors affecting transport-related social inequity, and also influences people’s travel behavior (El-Geneidy et al., 2016; Low et al., 2020; Zhao and Zhang, 2019). Undoubtedly, a growing number of people are commuting by public transport in Chinese cities. For instance, in Beijing, although private car ownership is still very high, 72% of people used public transport to travel to work in the central urban area in 2017 (BITI, 2018). More broadly, the total operating mileage of China’s metro system reached 5376.89 km in December 2018, while there were 41 cities served by the metro as of September 2019. However, it is argued that a distance-based fare may not be sufficient to reduce the travel demand for people who do not need to commute at peak times (Monday to Friday between 6:30 a.m. and 9:30 a.m., and between 4:00 p.m. and 7:00 p.m.). In other words, although some public transport users can travel at off-peak times, they may still choose to travel at peak-times, because they do not have to pay higher fares at the busiest times of the day; therefore, the current distance-based fare system is

not achieving the aim of reducing travel demand at peak times. In the case of London, passengers are charged higher fares if they travel at peak times, which may deter people from traveling during the rush hour if they do not really need to. At present, in most Chinese cities, public transport fares are still relatively cheap, in addition to being substantially subsidized by local governments, unlike in most cities in the global north. In addition, although some local governments have recommended that companies and institutions offer flexible working schedules, this has proved difficult for them to implement in reality, meaning that many people still need to travel at peak times.

Last but not least, in many areas of public life, nothing can be accomplished without norms or standards, and transport is no exception. In order to reduce the heavy traffic congestion and traffic-related injuries, traffic laws and regulations are essential to ensure that the overall traffic flow moves smoothly and people can travel safely. However, a proportion of pedestrians, cyclists, and drivers continue to violate the traffic rules. For example, statistically, the following megacities: Beijing, Shanghai, Washington, New York, London, Manchester, Tokyo, New Delhi and Mumbai, Beijing and New Delhi, witness the most traffic violations by motor vehicle drivers and pedestrians, as well as the highest numbers of traffic accidents. The main reason is that an individual who violates the traffic rules knows they are guilty but thinks that they will be fortunate enough to do so without incurring punishment. Indeed, those violations that are spotted are only punished mildly or in some cases not at all, showing that rules and regulations are not particularly effective in these cities. It was also found that most of the violations occurred in the peripheral areas in the case of Beijing and New Delhi (Baluja, 2008; Zheng et al., 2012). Hence, it can be argued that the level of punishment is currently far from sufficient to deter people. For instance, in Beijing, since the introduction of the new traffic law on 1st January 2013, the rules stipulate that drivers who go through a red light after that date will incur a fine of 200 RMB (1 GBP $\approx$ 9 RMB (Chinese Yuan)) and get a 6 point deduction (drivers with a total deduction of 12 points are banned) instead of the previous fine of 200 RMB with a 3 point deduction (MPS, 2016). In many places, drivers who break the rules are only fined 200 RMB if caught on camera, and do not have any points deducted. Clearly, traffic regulations and penalties are not an appropriate means with which to compel all commuters to obey traffic laws. Although these are still helpful at the current stage in most Chinese cities, educating people so that they understand the importance of obeying traffic laws is the ultimate goal.

In this respect, Tokyo offers one of the best examples that others can learn from. The “no jaywalking” regulation is largely adhered to by pedestrians, and designated pedestrian lanes are used by most pedestrians in Japan. In general, most Japanese people wait obediently at stoplights, although car drivers are held responsible even if an accident is primarily caused by pedestrians (HRDB, 2020). Top priority is given to the pedestrian in Japan, but most pedestrians and cyclists still comply with the traffic rules in any case. There are also fewer cameras used in Japan to capture violations committed by vehicles, cyclists or pedestrians. Additionally, in London, in order to reduce surface transport casualties, Camden council has produced a policy to educate young people about how to cross the road and stay safe when walking along the streets (Camden Council, 2020). Therefore, it can be argued that educating commuters to obey the traffic regulations and recognize the importance of sustainable transport development is vital. However, there are some questions about how this can be replicated in Chinese cities.

Discussion of Current Transport Planning and Management Strategies and Their Implications

In order to alleviate traffic congestion, reduce car usage and mitigate air pollution and CO₂ emissions, governments have adopted various efficient transport policy packages and strategies aimed at achieving sustainable transport development.

In terms of reducing car usage, the Beijing Municipal Government (BMG) has pursued a car registration plate restriction policy since 2008 that prevents vehicles whose last digit is 1 or 6 from driving on a Monday, vehicles whose registration ends in 2 or 7 from driving on a Tuesday, and so on, following a system of rotation. Furthermore, all private vehicles driving within the sixth ring road (urban areas, excluding the sixth ring road) and including Tongzhou District (excluding the main highways) which do not have Beijing registration plates must apply for a Beijing temporal pass (i.e. a Beijing entry permit) in advance, as well as limiting the maximum stay (including both driving and parking) in the urban area of Beijing and the Tongzhou District to 84 days per year from 1st November 2019 (China Daily, 2019). In addition, cars without Beijing registration plates are banned from driving within the fifth ring road at peak times even if they have a Beijing temporal pass. Moreover, a licence plate lottery system has been in force since 2011 in order to curb the rapid growth in purchases of new vehicles in Beijing. Under this system, a purchase permit draw usually takes place once every two months (the lottery was held every month before 2014) for potential vehicle buyers. Similar licence plate lottery schemes have also been rolled out in other cities, such as Shenzhen, Shijiazhuang, Guangzhou, Hangzhou, Tianjin, Guiyang, and Hainan. Moreover, a congestion charge scheme represents one of the most efficient approaches to managing transport demand, which has been successfully applied to reduce urban traffic jams within congestion charge zones in several international cities (Börjesson and Kristofferson, 2018; TfL, 2008, 2018; Wu et al., 2017). Beijing is currently planning to introduce a congestion charge (Liu et al., 2019), following in the footsteps of Singapore, Oslo, London and Stockholm. However, because the urban fabric and design rule does not permit CCTV cameras to be hung on a frame over or next to a road, in an unsightly manner, this has now been delayed.

In order to reduce traffic jams and car usage in Shanghai, an auction system has been used to maintain a set quota of new vehicles since 1994. In September 2019, it was announced that 149,507 candidates took part in Shanghai’s auction system, but only approximately 6% of them were successful. The average price of a car licence plate in Shanghai was 89,637 RMB in September 2019. Similar car registration plate auction policies have also been rolled out in other cities, such as Tianjin, Guangzhou, Hangzhou, and Shenzhen. Such schemes may also raise other issues in relation to transport-related social inequity (Cao and Hickman, 2019a; Cao et al., 2019; Cuthill et al., 2019; Knotts, 2019), although this point is not discussed in this chapter. However, it is still worth

Figure 1 Beijing cycle expressway.

Figure 2 Origin-destination commuting trips by dockless bikes (sample: "Mobike") in Beijing on 28 October 2017 between 8:00 a.m. and 8:30 a.m.

thinking carefully about who the winners and losers are in the car usage reduction process. It is likely that the better-off and higher-income cohorts will be the main beneficiaries.

Active travel promotion, such as dockless-bicycle-sharing programs and/or segregated cycle lane development, is one of the most successful approaches that has been implemented in terms of achieving sustainable transport development in many Chinese cities (Cheng et al., 2019; Gu et al., 2019; Jia and Fu, 2019; Zhang and Mi, 2018). The wider positive impacts, such as reducing traffic jams, air pollution, and CO₂ emissions, and improving people's health (e.g., reducing obesity), can clearly be attributed to encouraging active travel via cycling and walking (Aldred et al., 2019; De Vos et al., 2016). For example, the first Beijing cycle expressway opened on 31st May 2019, covering 6.5 km, and connects Huilongguan to Shangdi in Northern Beijing (see Figs. 1 and 2). It offers safe, convenient and fast travel to over 8000 commuters daily. However, it has been argued that active travel may be more effective in addressing the "first mile" and/or "last mile" of Chinese commuters' journeys, particularly in the megacities, rather than making the whole trip by bicycle or on foot. For example, Fig. 2 shows that most of the origins or destinations that people travel to or from using dockless bicycles (e.g., Mobike) corresponded to the subway stations in Beijing. A possible explanation for this is that Beijing is a

large city covering an area of 16,410 km². Therefore, it has different mobility challenges in terms of active travel, compared to London for example, which covers an area of only 1577.3 km², meaning that people can complete their entire commute by bicycle and/or on foot. In 2018, the average commuting time for Beijing commuters was 56 min within the sixth ring road, and the average travel distance was around 12.4 km (BTI, 2019). Therefore, it is difficult for cyclists or pedestrians to commute from their home to their workplaces, especially if they live in any of the Chinese megacities such as Beijing, Shanghai, Tianjin, and Shenzhen. In some tier 3 or 4 cities, or relatively small-scale Chinese cities, pro-active travel would be more feasible. However, it is essential to provide the necessary support facilities, because it may be too expensive for these smaller cities to invest the required amount in cycling infrastructure. For example, in the UK city of Nottingham, it would cost around £1 million to build a one-mile segregated cycle path (1 GBP ≈ 9.2 RMB (Chinese Yuan)). This means that the local government and/or transport authority are more likely to reject the transport appraisal proposal to build a cycle highway, particularly in a tier 3 or 4 city, as the conventional cost–benefit analysis model is still widely applied to evaluate mega transport projects in China, and even in the UK (Hickman and Dean, 2018; Spurling et al., 2019; Vickerman, 2017). Last but not least, the management of dockless bicycles also constitutes an issue for most Chinese cities, primarily because of oversupply (Lyu et al., 2020), arbitrary parking (Zhang et al., 2019), and repair and recycling (Lyu et al., 2020). It is evident that the advantages and disadvantages need to be carefully considered and balanced when implementing strategies to tackle transport issues.

Finally, but no less importantly, land-use planning and urban structure can significantly influence travel demand and behavior (Hu et al., 2019). A higher range of densities, pedestrian-oriented design, mixed land-use, improved travel demand management, and an increased level of accessibility always play a key role in shaping sustainable transport development (Cervero and Kockelman, 1997; Ewing and Cervero, 2001, 2010; Hickman et al., 2010). In China, sustainable urban planning and land-use policies have already been taken into consideration by decision-makers and urban planners in order to meet sustainable urbanization goals (Xu et al., 2019). For instance, the collaborative development strategies in Beijing, Tianjin and Hebei (also known as the Jing-Jin-Ji project) will not only boost local and regional economic growth, but also dramatically improve the levels of accessibility between each city (Sheng et al., 2018). However, it should also be noted that a lesson can be learnt from the case of Tongzhou, a dormitory satellite town of Beijing. In order to help reduce traffic congestion within Beijing, the Beijing Municipal Government (BMG) tried to develop several new satellite towns with good quality links to the existing city centre, with the aim of dispersing traffic and reducing population overcrowding (see Kong et al., 2005, for more details of the Beijing Master Plan 1991–2010). In theory, a satellite town should be able to be selfsupporting, selfresourcing, and selfsufficient. However, in reality, Tongzhou has been transformed from a satellite town into a dormitory town due to the job–housing imbalance issue, partly caused by unaffordable house prices (Housing affordability has already been identified as a social issue (Edwards, 2016)); however, it has not been recognized and/or analysed together with the joint effects of transport and housing costs (Cao and Hickman, 2018; Guerra and Kirschen, 2016; Liu et al., 2020)) in the central area of Beijing, as well as generating a high “tidal traffic flow” at peak times between Tongzhou and Guomao (Central Business District in Beijing). In an attempt to mitigate this problem and relieve some of the pressure on Beijing, the BMG has moved a number of state-owned companies, schools, hospitals and industries to Tongzhou. It is expected that approximately 400,000 people will have moved from the central area of Beijing to Tongzhou by 2020. It is hoped that this policy-oriented action will help turn Tongzhou into a proper satellite town and subcenter of Beijing, thereby reducing some of the overload on central Beijing.

Conclusions

This chapter has reviewed the history of transport development in China and critically discussed the status quo and some current transport planning and management strategies and their implications. The key findings show that, although investment has been made in the transport infrastructure, with the network being extended, and some effective transport strategies being rolled out, traffic issues persist in many Chinese cities. Although significant efforts have been made to address some of the main traffic problems, the goal of sustainability remains unfulfilled. In addition, mitigating strategies and transport planning approaches may not always be directly replicable from developed countries to developing countries, at least in the Chinese context.

This chapter makes two main contributions to both academia and practice. In the academic context, the review and critical discussion of the status quo and current strategies applied to tackle traffic issues can contribute to the international literature in order to enrich our understanding of transport planning and management, particularly through the lessons learnt from Chinese cities. In practice, it can make transport planners and policymakers aware of the importance of understanding and implementing both government policy- and people-oriented strategies to achieve sustainable transport development, as well as taking the unexpected and/or potential side-effects into consideration when making transport policy decisions in the future.

It is argued that wherever there are cities in China, there will be an indefinite demand for road capacity over the next couple of years following the current trajectory of the “business as usual” model. Therefore, it is imperative to implement sustainable transport strategies, manage travel demand, and integrate land-use planning and transport via a top-down strategy. In addition, I would argue that implementing top-down-oriented transport planning strategies (e.g., transport demand enforcement and management) may only temporarily reduce car usage and mitigate traffic congestion in the short term. In order to achieve the ultimate goal of sustainable transport development in the long run, the most important thing is to change the perceptions and awareness of people who use motorized vehicles, and enable them to realize the fundamental significance of using sustainable transport modes (e.g., public transport, and cycling and walking) and in turn help to create sustainable and liveable cities in China.

The Road Safety Problem

Key Global Statistics

Road traffic crashes constitute a major global public health problem, since each year 1.35 million people are killed in road crashes worldwide. According to the World Health Organization, road traffic injuries are the 8th leading cause of death for people of all ages and the 1st cause of death among children and young adults (5–29 years old).

Over the last 15 years, the number of road fatalities has increased from 1.15 million to 1.35 million, while the fatality rate per population has remained stable at almost 18 fatalities per 100,000 population. The respective rate per vehicles has reduced more than 50% (from 135 fatalities per 100,000 vehicles in 2001 to 64 vehicles per 100,000 vehicles in 2015), while the number of motorized vehicles increased during the same period (WHO, 2018).

However, the burden of road traffic injuries is not distributed proportionately among the countries. As shown in Fig. 1, the low and middle income countries account for 85% of global population and 60% of registered motorized vehicles, however, the vast majority of road fatalities (93%) have been recorded in these countries.

From a geographical perspective, the highest rates of road traffic deaths were recorded in Africa (26.6/100,000 people) and in Asia-Pacific group (19/100,000 people). On the contrary, Western European and other countries had the lowest fatality rate with 8.2 fatalities per 100,000 population. In terms of road safety progress, the road fatalities per population have increased in all regions during the last three years, except the Eastern European and the Western European and other countries (Fig. 2).

Finally, great variations are also found in the types of road users killed in road crashes. At a global level, more than half of road fatalities concern Vulnerable Road Users (VRUs), and more specifically, 28% were Powered Two Wheelers (PTWs) riders, 23% were pedestrians and 3% were cyclists. Moreover, the highest percentage of pedestrian fatalities was recorded in African and Eastern Mediterranean countries, while in South-East Asia and Western Pacific the majority of road fatalities were PTWs (WHO, 2018).

Road Safety and Macroscopic Developments

Historically, the level of motorization has been proven to have a nonlinear correlation with road crashes (Kopits and Cropper, 2005). Early experiences from industrialized countries suggested that, while the level of motorization increased, the number of road fatalities also increased, due to the increased traffic and related speeds enabled by developments in vehicle technology and road infrastructure. However, a “breakpoint” was observed, roughly situated during the 1970s in most countries, after which the level of motorization still increased but the number of fatalities showed a decreasing trend; this was attributed on the one hand to the increase in congestion in industrialized countries (hence lower speeds) and on the other hand to the awareness created among stakeholders in these countries on the need to address the road safety problem, leading to the first wave of coordinated efforts. Several countries exhibited a similar pattern, although slightly shifted to later in time, depending on their patterns of economic growth (Yannis et al., 2011).

Figure 1 Proportion of population, registered motor vehicles, road network and road fatalities by country income category, 2016. Source: IRF-WRS (2018), WHO (2018) and World Bank (2018).

Figure 2 Fatality rates per population in the UN Regional Groups in 2013 and 2016. Source: WHO (2018); <https://www.un.org/depts/DGACM/RegionalGroups.shtml>.

A similar correlation is observed with respect to economic indicators such as GDP per capita and unemployment—all reflecting economic growth, social welfare, as well as cultural developments.

It should be noted, however, that a short-term relationship exists between road safety and economic recessions. When GDP per capita decreases, the number of road fatalities also decreases, as a result of reduced traffic exposure of all road users. Once economic growth resumes, the number of fatalities soon returns into an increasing trend. This pattern was recently validated in several studies dealing with the economic recession of 2008–15 in Europe and other industrialized countries (Yannis et al., 2014), as a short-term fluctuation within the macroscopic trend described previously.

The understanding of the macroscopic relationship between road crashes and economic growth is particularly important when considering the economic development expected in the next decades in the low- and middle-income countries. Many of these countries are a long way from reaching the “breakpoint” of the level of motorization at which road fatalities start to decrease, therefore the global road safety problem is expected to dramatically worsen, and there is urgent need for proactive action.

The Road Safety System

The road safety system includes three distinct components: the road user, the vehicle, and the road environment. Road crash investigations have shown that human factors are the main contributory factor in more than 65% of road crashes, and one of the contributory factors in more than 95% of road crashes (See Fig. 3).

Figure 3 Overview of crash contributory factors. Source: NSW Roads and traffic Authority (1996).

A fourth component concerns the structural and operational characteristics of the system (including legislation and rules, cultures, and general socioeconomic elements), which affect the human-vehicle-road interaction; this is referred to as road safety management. In the following sections, each of the components of the road safety system is analyzed, following an introduction to the basic definitions and theories of road crash risk.

Road Safety Risk

Definitions of Risk and Exposure

The number of fatalities and injuries alone are seldom sufficient, and can even be misleading when assessing road safety problems; risk estimates are needed. Road risk can be generally defined as the probability of crash/fatality occurrence.

This definition draws from the probabilistic background of road crash occurrence; road crashes can be considered as the result of binomial (Bernoulli) trials, with two possible outcome (success or failure), and the Poisson theorem of crash counts consolidates the sum of these trials as a Poisson-distributed random variable. This is an imperfect consideration, although in several cases for practical purposes a Poisson distribution can be assumed. From a statistical viewpoint, a Poisson distribution has a basic property of the equality of its variance to its mean. When crash counts are over- or under-dispersed, it has been shown that a mixture of Poisson and Gamma distributions may best describe the process of crash occurrence, resulting in a Negative Binomial distribution (Hauer, 2001).

In the recent years, developments in statistical and econometric modeling have allowed to overcome many of the limitations of conventional models. For instance, the zero-inflated Poisson model may account for the presence of many zero counts in the data (Lord et al., 2005). Hierarchical, or multilevel, or mixed effects models may account for unobserved heterogeneity and other dependences among crash observations (Huang and Abdel-Aty, 2010).

The role of exposure in the estimation of road risk can be understood when considering the nature of Bernoulli trials. At an aggregate level, however, the number of crashes depends on the number of trials (and the trials cannot be considered as being independent).

If continuous measurements of exposure are available, risk can be defined through a function mapping road safety outcomes onto exposure. Within this “continuous” risk approach, crash occurrence will be modeled as a Negative Binomial model with the following general form, also known as Accident Prediction Model or Safety Performance Function:

$$N_i = L \times e^{[a+b \times \ln(c \times \text{exposure})]}$$

N_i is the predicted average crash frequency crashes in road segment (i); L is the segment length (in km); exposure is most often expressed through the annual average daily traffic [AADT - vehicles/day]; and a , b , c are coefficients to be estimated.

Continuous exposure measurements are not always possible, and therefore a “discrete” risk approach may be opted for, in which risk is defined as an (incidence) rate: the number of crashes divided by the amount of exposure over a given time period (Papadimitriou et al., 2013).

In practice, there are different measures of the amount of exposure, all with different advantages and limitations, but can be broadly classified in two groups:

- Traffic estimates: vehicle-kilometers of travel, road length, fuel consumption, and vehicle fleet.
- Persons-at-risk estimates: person-kilometers of travel, number of trips, time spent in traffic, driver population, and population.

Although any of the above indicators could be a pertinent approximation of exposure in certain contexts (e.g., fuel consumption for macroscopic analysis, population for epidemiological analysis, and road length for developing countries), the number of vehicle- and person-kilometers of travel is widely considered as the optimal measure.

Despite important efforts at national and international level, the lack of exposure data remains one of the main limitations of the potential for reliable and evidence-based road safety analysis. While exposure data (in the form of traffic flow/AADT) are largely available for the main interurban road networks and the main vehicle types, the measurement of exposure in urban areas and for road user characteristics is much more scarce.

Confounding Factors in Risk Assessment

Road crashes are rare probabilistic events. Due to the randomness involved in the crash process, it is often observed that crash counts tend to fluctuate around an “expected” value. This is called regression-to-the-mean and unless taken into account it may lead to misunderstanding of safety developments, especially over a short time period. Moreover, there are time dependences in the occurrence of crashes, both in the macroscopic level (long-term developments) and in the form of serial correlations. Also, the occurrence of crashes is not independent from the amount of exposure and other external factors.

The Empirical Bayes method (Hauer, 2001) is widely used in order to obtain the best estimate of the “expected” number of crashes. The Empirical Bayes method uses on the one hand a model-based estimate of crashes through a Safety Performance Function (SPF) developed on the basis of historical data from a large number of similar locations (taking thus into account long term trends and external factors), and on the other hand the observed value of crashes in a given location. A weighted estimate is made, and the weighting factor can be calculated for the specific sample, taking into account the size of the sample and the dispersion of the crash counts.

Risk Assessment Through Traffic Conflicts and Surrogate Safety Measures

A traffic conflict is defined as an event involving at least two road users, where one road user makes a nontypical maneuver (e.g., harsh maneuver, traffic rules violation) resulting in a crash avoidance maneuver from the other road user. Several studies have shown that the number and types of traffic conflicts correlate very well with actual crashes in many contexts (Polders and Brijs, 2018). Moreover, traffic conflicts are directly observable (although not always measurable in an easy and straightforward way), and therefore analyses can be proactive (i.e., identify risk scenarios before actual crashes occur) and/or allow a faster appraisal of the safety impact of a treatment, without waiting for several years of crash data to become available) (Ismail et al., 2010).

Several traffic conflict techniques are available, all based on criteria for observing and classifying traffic conflicts based on their criticality/severity. The indicators used are referred to as “surrogate safety measures” and typically include (but are not limited to): TTC—time to collision; PET—post-encroachment time, deceleration rates, and so on.

In the recent years, the availability of traffic observations through cameras, and the developments in video image processing have boosted the potential of traffic conflicts analyses, with numerous applications on intersection safety, interactions between vehicles and VRUs, and so on.

Road Safety Management

Structure of Road Safety Management Systems

The road safety management system is often described as a “pyramid” with five layers hierarchically structured as follows:

- Structural and cultural characteristics (i.e., policy input) at the bottom level, which reflects the “results focus” of stakeholders.
- Resulting safety measures and programs (i.e., policy output), at level 2.
- An intermediate layer specifying the operational level of road safety, through key performance indicators (KPIs) on issues like speeding, drinking, and driving, as well as state of the road network and the vehicle fleet.
- Final outcomes expressed in terms of road casualties are then observed (level 4).
- The top of the pyramid includes an estimate of the social costs of road crashes.

This concept was initially presented and further developed by different stakeholders within the decade 2000–10, and is still widely used for the planning of interventions for road safety improvements, although it concerns only a “snapshot” in time, and the time component has not been integrated (see Fig. 4).

Therefore, road safety management has a structural/institutional component, as well as an operational component. The structural component involves the establishment of a strong Lead Agency and an efficient intersectoral coordination (as road safety is a typically multisectoral problem). In this framework, a vision and strategy for road safety are the backbone of road safety policies (policy input). At the operational level (policy output), these are translated into specific programs and measures.

Effective road safety management systems need to be evidence-based. This implies the availability of data and tools for safety analysis. Evidence-based approaches can be quantitative or qualitative, but should follow the hierarchical process of road safety management. In this framework, KPIs are the key component and possibly the weakest link along the various stages of the evaluation—partly due to the difficulty in systematically collecting the necessary data.

Safe System Approach

While historically the emphasis of road safety policies was to tackle the “human error” as the main cause of crashes, in the last couple of decades a new approach is developed. The “safe system” approach shifts the traditional blame from the human, and introduces

Figure 4 Generic structure of road safety management systems. Source: Koornstra et al. (2002) – left panel, Bliss and Breen (2009) – right panel.

the concept of “shared responsibility”: (1) system designers to accept responsibility for road users safety, (2) responsibility taken by vehicle manufacturers for investments in safety research, and (3) those that use the system accept responsibility for complying with the rules and constraints of the system.

The safe system approach underpins several road safety visions, namely the Swedish “Vision Zero” which, in addition to the shared responsibility concept, introduced the moral unacceptability of loss of human life, and the adaptability of roads, streets, and vehicles to human capacity and injury tolerance. The vision, although adopted by many countries, has also been criticized for socio-economic inefficiency (due to very high costs) and ethically questionable restrictions of freedom, privacy, and autonomy.

A milder version of the safe system approach has been expressed in the Dutch Sustainable Safety vision, in which the road infrastructure design by itself should inherently and drastically reduce crash risk (see Section 5). In addition, a “social” forgiveness dimension is introduced, including a willingness to anticipate and “forgive” a potentially unsafe action of other (less competent) road users.

Safety Impact Assessment

The road safety policy-making cycle includes a number of stages: (1) risk assessment/risk identification, (2) identification of causes of crashes, (3) selection and prioritization of measures/programs, (4) implementation of measures/programs, and (5) evaluation of the impact of measures/programs. The evaluation stage should also inform on new or pending risks, re-initiating thus the cycle.

The aim of road safety impact assessment is to yield quantitative estimates of crash/risk reduction. The most common relevant quasi-experiments are observational before-and-after studies (Hauer, 1997), in which the development of crashes in a treatment site/area is compared to that of a number of sites/a wider area with similar characteristic—in order to control for regression to the mean and other confounding factors. The estimated odds-ratio has as nominator the odds of crashes in the treatment site after the treatment to before the treatment, and as denominator the respective odds in the control group. The odds-ratio is also known as Crash Modification Factor (CMF); a CMF > 1 indicates an increase in crashes, while a CMF < 1 reflects a reduction in crashes. The percentage crash reduction is then calculated as $(1 - \text{CMF}) \times 100$. CMFs are also used (as multiplicative factors) in order to adjust a SPF on the basis of site-specific geometric and operational characteristics.

Once the safety impact of a measure is known, the socio-economic impacts are often estimated in monetary terms by means of cost-benefit analysis (CBA). CBA of safety treatments may be complicated due to lack of robust data on measures’ costs and benefits, and is generally criticized for ignoring the distribution of costs and benefits among different groups, the monetization of human life for statistical purposes, and other ethical issues. However, it remains a key tool for evidence-based approaches aiming to assess and compare policy alternatives.

Road User

Road users participating in traffic are exposed to risk in an asymmetric way. By nature, the difference in mass, protection and speed of the different traffic participants induces a different “baseline” fatality risk (Dupont et al., 2010): nonmotorized road users such as pedestrians and cyclists are far less protected than passenger car occupants. PTW riders combine the lack of protection with increased speed, exhibiting thus increased risk. On top of that asymmetric “baseline” risk, human factors, including personal characteristics (age, gender, experience, etc.), intrinsic characteristics (perceptions, attitudes, motivations, etc.) and behavioral characteristics (e.g., risk-taking, compliance, behavioral adaptation) significantly affect risk.

Figure 5 Human body tolerance to physical force. Source: Based on [Tingval and Haworth \(1999\)](#).

In general, males have a higher risk of crash involvement. Young people are more likely to be involved in crashes; this is due to a combination of inexperience (novice drivers) and age-related personality elements (e.g., low risk perception, underestimation of risk, over-estimation of skills, peer pressure, increased likelihood to drive under the influence of alcohol/drugs, and so on). Driver training and licensing procedures aim at reducing the risk of novice drivers, namely through “graduate licensing” schemes; an initial “probation” period is set for novice drivers, in which driving is allowed under specific condition for example, daytime only, accompanied driving, and so on.

Risk also increases for older people (>65 years old), as a combination of physical vulnerability (and thus increased risk of injury once involved in a crash) and physical or cognitive impairments that may be due to natural consequences of ageing, or medical/neurological conditions that are more prevalent among the elderly. The increased risk of elderly people is to some extent an artifact created by their reduced traffic participation (i.e., low exposure). Periodic medical testing is in place for older drivers, in most cases together with fitness-to-drive assessment procedures (regular or upon medical referral) with on-road tests at dedicated facilities. These fitness-to-drive assessments are often criticized for lack of objectivity in the evaluation, due to a lack of common framework, and concrete quantitative measures of driving performance.

Regarding behavioral factors, speeding is commonly known as the major risk factor affecting not only crash risk but also crash severity. The “safe system” approach stresses the human body tolerance to a collision as a function of impact speed (see [Fig. 5](#)). Driving under the influence of alcohol or drugs remains a major issue and crash contributory factor in most countries. The nonuse of restraint systems (seat belt, child seats) and protective devices (helmets, reflective clothing) are also major causes of road fatality.

Distraction and inattention have been consistently recognized as important crash contributory factors. Sources of distraction may be in-vehicle (operating navigation or entertainment systems, eating, or drinking etc.) or external (from observing landscape to simply daydreaming). However, the major source of in-vehicle distraction is the use of mobile phone while driving, which may increase crash risk by four times—and the use of hands-free devices does not appear to bring any benefit in most cases ([Caird et al., 2008](#)). Moreover, behavioral adaptation (a.k.a. risk compensation) through speed reduction is not sufficient to counterbalance the distraction-related impairments.

Human factors and road user behavior are mainly studied through three methods: (1) simulator studies, which allow for a controlled and ethically acceptable experimental environment, but with decreased physical validity, (2) naturalistic driving experiments, based on monitoring real driving behavior through instrumented vehicles, which allow for real driving patterns to be explored in detail, however with a high implementation cost and huge data processing needs, and (3) survey instruments aiming to understand intrinsic factors underlying the observed behavior, which are cost-effective but suffer from the known limitations of self-reported information.

The Road Environment

In general, in interurban/rural areas there are fewer number of crashes, but higher numbers of fatalities, whereas the opposite is the case in urban area crashes. There are well-established relationships between geometric design features, such as horizontal and vertical curvature, cross-section design (lane/shoulder width, superelevation, etc.), roadside treatments and pavement conditions, all taken into account in national road design guidelines.

Within the “safe system” approach (see Section 3.2), the concept of predictability of roads has emerged; this is defined as the consistency and continuity in road alignment, avoiding abrupt changes and thereby allowing drivers to properly align their expectations and behavior (“self-explaining roads”). This is combined with a concept of forgiveness in road design; “forgiving”

roads (and roadsides) are designed in a way that human error is anticipated and measures are taken so that this error does not result in a fatality or serious injury (e.g., obstacle-free zones, crash cushions, median separation).

The implementation of road design standards does not by itself guarantee safety (ITF, 2015). A continuous management of infrastructure safety is needed, through actions such as road safety audits, road safety inspections, identification and treatment of high risk sites, network safety management, and so on.

At the operational level, traffic flow and speed are the key factors that affect the level of safety. As shown in Section 2, the typical SPF implies a positive correlation between traffic and crashes. Moreover, speed management is one of the most important elements of infrastructure safety management. Speed limits should be credible, consistent, and relevant to the functional class of the road. Within a “safe system” approach, speed limits should prevent the exposure of humans in collision forces that would be physically intolerable. Especially in urban areas, there is a strong tendency to develop 30 km/h zones around areas with increased VRU traffic; this is often combined with traffic calming engineering treatments such as speed humps, raised crossings, woonerfs, and so on.

Environmental factors may also play a role: weather conditions have an impact on crash risk, although not always in a straightforward manner. Most studies suggest a risk reduction with precipitation, and a risk increase with extremely high or low temperatures. It is suggested that the decrease in crashes during rainy conditions is a result of reduced exposure.

The Vehicle

Although the vehicle has a minor role as crash contributory factor, the developments in active and passive safety have contributed to the substantial improvement of road safety outcomes. Active Safety Systems (also commonly known as Advanced Drivers Assistance Systems) play a preventive role in mitigating crashes by providing advance warning or additional assistance in steering/controlling the vehicle. Head-Up Display (HUD), Anti-Lock Braking Systems (ABS), Electronic Stability Control (ESC), Lane Departure Warning System (LDWS), Adaptive Cruise Control (ACC), Blind Spot Detection (BSD) and Night Vision System (NVS) are common Active Safety Systems – and most have been proved very effective in safety impact evaluations.

Passive Safety plays a role in limiting the injuries caused to road users in the event of a crash: airbags, seatbelts, Whiplash Protection System, and so on. In this context, vehicle crashworthiness, that is the ability of the vehicle to protect its occupants during an impact, has received particular focus through crash tests of typical scenarios. The New Car Assessment Programme (NCAP) and its star rating of vehicles provide a concise depiction of the level of safety of the current vehicle fleet.

In recent years, the vehicle is found at the center of road safety developments, through the important research and pilot testing of connected and automated vehicles (CAV). Six levels of automation are considered, ranging from no automation (Level 0), to driver assistance (Level 1), to partial automation (Level 2), to conditional automation (Level 3), to high and full automation (Levels 4 and 5). In all except Levels 4 and 5, the human driver maintains a strong supervising role over the autonomous system (SAE, 2018).

Safety has been a key “banner” value for the deployment of autonomous vehicles, but it is proved very difficult to responsibly claim it, as current evidence is insufficient (ITF, 2018). The challenges of mixed traffic conditions (conventional vehicles sharing the road with automated vehicles) remain to be addressed, as well as aspects related to the interaction of CAVs with pedestrians, cyclists, disabled people, and so on.

Most importantly, the interaction between human and machine, especially in intermediate levels of automation, is expected to create new safety issues. As humans are not good at passively monitoring systems, the so-called “out-of-the-loop” (OOTL) problem is highly likely. During OOTL, humans become inattentive and lose situational awareness of the driving task. This becomes critical when an authority transition is triggered by the system (e.g., due to an emergency situation, a sensor deficiency, or simply because the system reaches the boundaries of its Operational Design Domain). In this case, the takeover performance of human drivers appears to be compromised by several personal and external factors, with uncertain safety consequences.

Therefore, further research is required in order to prove the improved safety of CAVs and the conditions for their safe deployment. It is expected that an iterative process of increased penetration rate leading to increased trust, leading to further increase in penetration rate, and so on, will be required, until a critical mass of CAVs is reached—a point at which safety benefits are estimated to be maximized. On the other hand, increased trust to automation should be also understood as “properly aligned” trust; over-trust (over-reliance) to automation may lead to mis-use of the system, while the lack of trust may lead to dis-use.

Future Road Safety Perspectives

Despite the wealth of scientific knowledge available, road safety remains to some extent poorly understood: a typical example is the often misunderstood relationship of traffic exposure and speed with crash risk. Other key road crash contributory factors (i.e., alcohol, distraction) have not been fully addressed, and VRUs are not safely integrated in many urban traffic contexts.

From a policy perspective, despite important progress, there is need for further strengthening of road safety cultures and the “safe system” approach. Safety monitoring and evaluation are only fragmentarily implemented, often resulting in important investments not bringing results. Finally, road safety remains poorly integrated within other sectoral policies, namely mobility, energy/environmental and health. The above challenges are still relevant in all countries, and especially in LMIC.

New technologies and digitalization in transport have the potential of bringing dramatic safety improvements, however more research and evidence is required to responsibly manage the transition phase to higher levels of automation properly integrated

within new models of transport operations in urban and interurban areas. Regarding the safety of automated vehicles, it should be kept in mind that zero crashes cannot be envisaged - on the contrary, certain new crash mechanisms are to be anticipated.

Importance of Mobility in Later Life

In almost all higher income countries across the globe, along with an increasing number of lower to middle income countries, a lower birth rate coupled with people living longer is creating an ageing society. In an ageing society, the population is getting older both in absolute numbers and in the higher proportion of older people within their total population. In 1950, there were only 384.7 million people aged over 60 years, representing only 8.6% of the global population [(UN (United Nations), 2015)]. There are now around 840 million people over 60 across the World, representing 11.7% of the population. By 2050, the world's population of people aged over 60 years will nearly double to 22%.

The way we live our lives as we age is also changing. Older people are more active and more mobile than ever before. They are more likely to be working and playing important roles in society than recent generations. Hence, transport is more important to older people than ever before. People become more dispersed from one another, having moved around for work or leisure throughout the life course, with connections all over the country and even internationally. As people age they want to stay connected to these different communities and also to family and friends that are widespread geographically and hence high levels of mobility are needed to achieve this. Coupled with this is mobility needed for older people to work or to support others who may have working or caring responsibilities. In high-income countries, some older people are able to have high amounts of leisure time and enough money to be highly active and hence highly mobile. Years of policies aimed at supporting high mobility, mean society is often geared supporting long distance travel, for example by car, high speed train or domestic airlines. Policies have led to shops and services agglomerating at the edge of city centres, along major trunk roads, freeways, or motorways, designed around access by car.

In many high-income countries life without a vehicle can become difficult and people can face social exclusion. In addition, the wider negative externalities of car dominant societies, such as air and noise pollution, severance of communities and road traffic collisions, injuries and deaths tend to be under acknowledged. For nondrivers, these are faced of course, with fewer benefits of using the car itself. Older people are more likely to want to reduce or give-up or some people end up having to give up their driving altogether (Musselwhite and Haddad, 2010; 2018). Hence, older people can result in being less mobile as they choose or have to drive less, which transport policy should be highly supportive of. One of the main aims of transport policy is to balance the negative externalities of the car with the benefits of hypermobility. Yet, older people tend to be forgotten in such policy, and transport policy has traditionally championed economic efficiency above other concerns. Policy has often assumed that space and distance are an inefficient inconvenience to be overcome, as quickly and efficiently as possible (Parkhurst et al., 2014). Concentration of transport policy and subsequent provision of resource is often geared around the working adult and inter- and intra-urban mobility with a focus on provision in core work hours 9–5 (Musselwhite, 2018a; Musselwhite and Curl, 2018). Over concentration on economic factors within transport (and associated) policy, means those viewed to be less economically active have their needs given lower priority. People in the United Kingdom aged 65–74 years are those most likely to be involved in voluntary activities (Parkhurst et al., 2014). Older people's work patterns may be different to those younger in age, whether in paid work or volunteering or caring for others, the need to travel often involve avoiding rush hour, if they can. Transport policy also prioritizes utility trips, for example, work, shopping, or visiting the doctors or hospital and space between these formal activities tends to be devalued (Cresswell, 2010; Cresswell and Merrimen, 2011). However, research suggests older people really value mobility for its own sake, to get out and about and see the world passing by, to pass the time of day in the company or being copresent with others, or of being in the world with others (Musselwhite, 2017). To incorporate older people's needs and behaviors within transport policy, a radical shift and a different approach is needed. This paper examines some different approaches that might have more success, including using a life stages approach to transport policy, a greater need to involve older people in transport planning, changing the vision, and understanding future mobilities.

An Example of Positive Transport Policy for Older People—Free Bus Pass in the United Kingdom

People aged over 65 years of age, or those of any age with a disability, have been entitled to travel free of charge on any off-peak local public bus service in England since 2007, thanks to the English National Concessionary Travel Scheme. Around 76% of all women and 79% of men take up the free bus pass in England, compared to 61% and 50% in 2005—the year before free local travel. [Humphrey and Scott \(2012\)](#) suggest that ownership of a free bus pass is higher (around 80%–82%) among those on lower income (less than £15,000). This group are also more likely to use the bus once a week than those on higher incomes who use it less frequently.

Unsurprisingly, the free bus pass increases bus use ([Mackett 2013a, 2013b](#)). The most commonly reported activity older people cite as their destination across all these surveys is shopping, followed by social and leisure, day trips, visiting friends then medical, meaning people are socially connected and hence reduce isolation ([Mackett 2013b](#)). [Mackett \(2013b\)](#) also notes how such journeys support volunteering and caring work older people undertake which would otherwise not take place. [Webb et al. \(2011\)](#) examined three waves of English Longitudinal Study of Ageing data (2004, 2006, and 2008) and found a link between eligibility of a free bus pass and increased use of buses. They also found those who used the bus more often also had a reduced chance of becoming obese, suggesting that using the bus is associated with physical activity such as walking to and from bus stops and allowing people to engage with more activity. [Dargay et al. \(2010\)](#) modeled bus use against what would have happened if no free bus pass had been introduced. They found journeys made are more numerous and also often longer in duration and distance ([Dargay et al., 2010](#)). The findings suggest the number of bus stages (groups of bus stops) traveled through by older people increased by 45.4% in rural areas and 26.5% in urban areas. Additionally, [Andrews \(2011\)](#) found 74% of his respondents stating that the free bus pass improved their quality of life and general well-being.

Use of Life Stages in Transport Planning and Policy

It has been noted that transport planning or policy should be placed around life stages (e.g., retirement from work, becoming a grandparent, and becoming a carer), but even within this context age per se is very rarely mentioned in policy discourse ([Avineri and Goodwin, 2010](#)). Significant events or transition points in people's lives present an important opportunity for intervening at some or all of the levels, because it is then that people often review their own situation and potentially change their behavior. Typical transition points include: leaving school, entering the workforce, becoming a parent, becoming unemployed, retirement, or bereavement ([NICE, 2007](#)).

Research has identified that transition points such as retiring from work can offer opportunity for changes in mobility patterns and even modal choice including the chance to try out alternative modes including walking or cycling ([Chatterjee and Scheiner, 2015](#); [Goodwin, 1989](#); [Jones et al., 2015](#)). [Burningham and Venn \(2017\)](#) describe this as a “moments of change” theory where disruption of norms of behavior can create opportunities for change of behavior and where life-course transitions such as retirement can trigger changes in a variety of aspects of everyday life such as energy use, travel and purchase of consumer goods. They also note that life-course transitions may be a point at which individuals pause and consciously reflect on the life style they want and make changes to move toward that life style.

Involving Older People in Policy-Making

[Phillips and McGee \(2018\)](#) note, “transport policies have traditionally been developed based on government priorities rather than community needs, resulting in a lack of services” (pg 232–233). They relate this in particular to two examples of indigenous populations being marginalized by current transport provision, citing older Maori people being excluded through infrastructure and design issues and land use and transport planning and older people from the indigenous populations of Australia being isolated through lack of culturally appropriate transport in rural areas. However, it is equally true of other places across the globe. In the United Kingdom, as in many other high-income countries, older people are marginalized from society by poor transport planning not meeting their needs. This is compounded further for older people in rural areas ([Mollenkopf et al., 2004](#); [Parkhurst et al., 2014](#); [Shergold et al., 2012](#)), those in deprived communities ([Buffel et al., 2012](#)) and those from black, Asian, and minority ethnic groups in urban areas of the United Kingdom ([Higgs and Gilleard, 2015](#); [Owen, 2013](#); [Rees et al., 2012](#)) all whose needs are even less considered in transport planning. To get more community involvement there should be not just a shift in attitude from transport providers but a whole change in philosophy, to recognize the value of more community involvement; to recognize that transport is about people and community first and foremost, and technologies, economics and engineering second. It also requires both the time and skill of individuals to get involved, along with the desire to want to get involved. For this to happen a number of different ways to get involved are needed along with reciprocation of getting something back from being involved; people must be able to see their input resulting in change.

Older people also want more involvement in transport planning and decision making ([Musselwhite, 2018a](#)). There is an increasing emphasis on involving people in policy making thereby democratizing decision-making. Public involvement in services, through collaborative codesign are beginning to take shape in urban design, urban regeneration, and in some aspects of town and country planning, for example, collaborative, redistributive urbanism and intergenerational urbanism ([Buffel et al., 2015](#);

Buffel, 2018). It is highly recommended that transport follows these models. In addition, other stakeholder groups from third sectors and charities need more involvement in transport planning to champion the needs of older people.

Many of the issues older people face in the transport system would benefit from engaging more closely with older people in policy making. This could be done in a variety of different ways. It is suggested that local groups could be mobilized to collect information on their local area and mapping key issues that can then be used by local policy and practice when redesigning and planning the local area. First this could be done through individual or group audits of local streets. Older people could audit their local streets identifying the general age friendliness of the area using tools such as OPERAT (Older People's External Residential Assessment Tool; Burholt et al., 2016) which identify need for crossings, speed control, such as traffic calming, speed cameras, etc., need for improvements and decluttering of pavements, and identification of the need for cycle paths. To complement auditing, local groups could organize interactive mapping sessions to plot and note and discuss key issues in a local community in relation to transport. These could be carried out annually or be in response to a new initiative or event. They can be bottom-up and driven by the community or top-down and introduced as a form of consultation from local authorities or transport service providers. To support this, new technology can help with the capture of transport issues in real time, helping to geolocate issues and capture them and aggregate them easily and efficiently. The problem with involvement includes representation. Certain groups of older people are much more likely to take part in such exercises and there is a need to mobilize and involve other sectors of the community who do not normally take part in such exercises. Hence, different techniques aimed at getting different people involved are suggested, for example some people enjoy group work, others would rather monitor the local area from home or at distance. Monitoring who has taken part and who has not against known local community figures, shows who is engaging and who is not and who needs to be targeted. Barriers to involvement need to be examined and where possible managed or reduced.

In addition, there is a need for the involvement process to feel less tokenistic. As well as information coming from older people themselves, information must be fed back from the decision makers, the local policy, or transport service providers themselves. That is not to say that every issue needs a comment but there needs to be some two-way dialogue taking place with some significant feedback coming from the authorities. Obviously managing expectations is important. It cannot be given that people will have all of their issues satisfied but a feeling that they are being listened to and a dialogue opened up to be honest about why certain issues are priorities and not others. It is suggested that the local authority dedicate some web space to such community groups to allow space for discussion and dialogue.

Cross-Sector Working to Develop Shared Planning and Policy

Transport does not sit in isolation from the rest of an individual's life. It is entwined with other societal influences and barriers. A particular issue that would help older people would be better scheduling of healthcare appointments, so they do not take place when older people cannot access them. An examples of this is reflected in hospital appointments before 9 am when the concessionary bus pass is not applicable and travel is not free. In addition, there is often much waiting around for appointments then waiting for hospital or community transport to be coordinated on the way from appointments. Hence, it is suggested that healthcare helps by asking about and coordinating patients travel arrangements as best as possible. There is potential here for new technologies to help with the scheduling of transport and potentially sharing of transport services for people accessing similar healthcare appointments and travel to neighboring residential locations. Where there are known events taking place that are put on for older people, transport information, and even transport provision needs to be well-thought about and brought together.

In 2014, the United Kingdom Transport Select Committee made a series of recommendations to improve transport services to isolated communities, including the idea of "total transport" which involved better use of existing transport resources, including hospital and school transport. For example, it was suggested that at times when vehicles are not in use, they could be used to fill gaps in local provision by taking a more coordinated logistical approach. Devon County Council was an initial pilot for Total Transport, working to improve nonemergency patient transport services in partnership with the local Clinical Commissioning Group. As well as making better use of local resources there is a central information service for both those who qualify for patient transport and those who do not—who are directed to community transport options.

Changing the Vision of Transport Policy

Another aspect to consider for transport planners is to start to vision the world differently. Too much transport planning sees the future landscape as business as usual, with only marginal changes. Huge changes are ahead due to an ageing population. It is possible that there will be a significant increase in the amount of mobility that older people are undertaking, both in total, as there are more older people within society, but also more mileage per person, as older people end up being fitter and healthier. The current 50–64 year olds in the United Kingdom, for example, spend the highest number of miles driving per person of any age group (DfT, 2019) and so are likely to want to carry on this mobility into later life, resulting in huge increases in the number of older drivers or the number of people giving up driving and using other modes. Older people in high-income countries are also likely to be working longer and later on in life than currently, putting additional strain on the transport infrastructure. How to manage this demand will require significant resources. Older people are likely to be more heterogeneous than ever, there will be a variety of people working

full-time and those who have retired from work, those very fit to those with long-term chronic conditions affecting health and mobility. Hence, there is more reason here to involve older people in making decisions about transport.

There is often an assumption that interventions aimed at older people need to offer a like for like solution to mobility. For example, the need to provide literal mobility to replace lost literal mobility as someone gives-up driving. But as Parkhurst et al. (2014) note, actual literal mobility may be met nowadays through virtual mobility by electronic means, online shopping, staying connected to family and friends via computer technologies, and mobile and telehealth solutions (Marston et al., 2019). In addition, Musselwhite (2018c) notes that older people may not want to be as mobile as they have been, and may replace literal mobility with imaginative mobility, thinking, and reminiscing about mobility or observing others' mobility from their home. Underpinning this, though, is a need to feel that they can be mobile at any point, the potential for mobility is important to older people (Metz, 2000). This level of perceived control over mobility helps older people feel more secure if something changed, or they faced an emergency, often related to health issues of themselves, or a friend or family member (Musselwhite, 2018b).

Transport Innovation, Older People and Policy

Looking ahead there are potential changes in transport innovation that may have huge effect on older people (Shergold et al., 2015). These may have different effects on different groups of older people. Autonomous vehicles are quite popular among older people wanting to maintain their hypermobile life, especially among those facing the prospect of giving-up driving (Musselwhite, 2019). However, this could further increase the distances needed for travel, especially if take up of autonomous vehicles is large. This could have a detrimental effect on local neighborhood services and shops. Thus, autonomous vehicles could change interpersonal spaces; the spaces for human exchange outside of home environments which is vital for community life (Musselwhite, 2019). Older people spend greater amounts of time in their local neighborhood closer to home and community and social cohesion which may be decimated if hypermobility is maintained or even enhanced by autonomous vehicles. There is a need to more closely involve older people in future transport scenario development, to examine how such changes as autonomous vehicles might impact on their lives, both positively and negatively. At present the discussions are largely technology focused and there is a need for a more nuanced discussion involving the impact of social aspects of such technology.

Conclusion

Overall, older people's needs and issues are not well represented in transport policy. This is because transport policy has traditionally championed economic productivity associated with transport, coupled with a mistaken belief that older people are less productive and their activity therefore is less essential to support. There is also the idea that older people might not need to have their transport needs looked after. Older people are now more likely than ever to be involved directly in work, continuing to work later on in life than previous generations. Also, older people's mobility supports other economic activity or reduces the economic burden of society, for example supporting the work of others by looking after grandchildren or volunteering and caring for others. Older people also want to be active. They want to stay connected to communities and to family, and to leisure pursuits and transport has to help them fulfill these needs, especially in a hypermobile society geared around the needs of highly mobile, car drivers. However, it is important to be wary of introducing planning and policy that simply fosters growth in hypermobility. In a world of balancing health and environmental sustainability, policy, and planning need to be more social in nature, more nuanced and hence involve end users more.

It is therefore suggested that older people's transport needs must be addressed through policy. As we live in an ever-ageing population, it is necessary to get an understanding of older people's transport issues and needs, and involve older people in policy formation aimed at resolving some of the issues and planning for a more age-friendly transport system.

Electric Mobility: From Niche Solution to Emergent New Regime?

Electric mobility (EM) technologies have been part of the mechanized and motorized transport system for some 130 years, but over the last quarter century EM has been propelled from a position of niche applications, albeit including some critical ones, to becoming the central tenet of a technology-led strategy for the transport sector to solve its growing contribution to the paradigmatic problem of global heating (Morgan, 2020; Parkhurst and Seedhouse, 2019).

The article frames an analysis of the changing role of EM with concepts from the “sociotechnical transitions” literature, and in particular that fundamental societal change occurs only when one “sociotechnical regime” (Geels, 2004) replaces another, the regime encompassing sociocultural, technological, scientific, market and policy facets and being the dominating set of practices and technologies at a given time. The regime can also be understood as part of a “multi-level perspective” with “niches” of alternative activity existing as “protected” from the stabilizing influence of the regime, and allowing for innovation, while the regime interacts with a “landscape” of features, which are resistant to influence by individual actors, such as the configuration of the built environment and infrastructure, or the dominant belief systems of society. The growing priority given to global heating is a contemporary example of shifting beliefs. Drawing on these concepts, the article evaluates the new importance given to EM to establish how far this change is part of a fundamental revision in the conduct of transport policy—a regime change—or simply the substitution of one technology for another, with the effect of stabilizing the current regime.

The following section considers how EM technologies emerged in a 19th century context in which innovations were also occurring in respect of power from steam and from internal combustion engines (ICE). From a position of technical competition, electrification retreats into specific niches as a regime emerges around the ICE, which in turn influences the landscape, reinforcing its stability. The third section then examines these niches in terms of their technical solutions, but concludes that the most significant challenge to the ICE regime by EM will rely on the rechargeable battery. Finally, the last section examines the case that EM is likely to displace the ICE regime, focusing on the key role of the private, owned, passenger car, as the dominant mode within a landscape which is physically car dependent and features strongly-engrained socioeconomic practices which maintain the car’s centrality.

Emergence of Electric Mobility Niches

Transport-sector applications were amongst the first practical implementations of the direct-current electric motor which emerged as an industrial technology in the 1820s and 1830s. From the start, the history of electric mobility cut across transport modes but was immediately in competition with other powertrain technologies.

The first demonstrations of electric rail traction were undertaken by Robert Davidson from 1837, little more than a decade after the Stephenson brothers inaugurated steam locomotion on the pioneering Stockton–Darlington railway in northern England (Day and McNeil, 1996). Although the battery technology deployed by Davidson would eventually become a rarity, electric rail transport would in the 20th century become the most important set of EM niches.

The development trajectory of small electric watercraft shares commonality with the rail systems. Experimentation began in the 1830s into battery power for small boats via paddlewheel or propeller, and they subsequently became commonplace until ICE power dominated after 1920 and electric power retreated to a few small niches, such as service on inland bodies of water where environmental regulations prohibited ICE or steam power.

Although early battery technologies created significant limitations on the application of EM, in the road domain steam power faced very significant safety and practicality constraints on networks prioritized for horse-drawn traffic, while ICE development was subject to a number of technical barriers. Indeed, the technologies underpinning battery–electric (BE) and ICE road vehicles—both niche modes in this period—show similar development trajectories through the middle half of the 19th century.

In the case of the electric vehicle (EV), the invention of the rechargeable lead-acid battery by Gaston Planté in 1865 was a critical step, with Thomas Parker's first BE car of 1884 thought to have preceded Karl Benz's first ICE car by a year, with Parker's first electric bus following in 1886 (Guarnieri, 2012). A photograph of Parker's car shows a four-wheel "horseless carriage" with three passengers aboard and an altogether more solid appearance than Benz's tricycle; a difference which presages the next 20 years of development. The first vehicle of any kind on road or rail to exceed 100 km h^{-1} , in 1899, was an electric car. More battery cars were in circulation in 1900 than ICE cars, with performance both in range (30–50 km) and speed $15\text{--}25 \text{ km h}^{-1}$ being competitive with contemporary ICEs. Electric vehicles provided taxi services in New York and postal deliveries in France, where electric car production was most developed. Guarnieri (2012: 6) identifies electricity as the "high tech" fashion of the time, with the electric car as a key symbol of the success of positivist science, offering a "silent, odorless, reliable, simple to drive, and easy to start" alternative to both ICE and steam road vehicles. Ferdinand Porsche is primarily remembered for his design of the Volkswagen Beetle and the eponymous sportscar company, but his first car, in 1899, was electric.

However, during the 1900s the "balance of power" between the two technologies began to change. Notable, given that it remains a competitive disadvantage a century later, electric cars in the 1910s were costly not only in absolute terms, but in the United States at least, bore a two-and-a-half-to-five times price premium over ICE cars, and were therefore a luxurious, exclusive option (Guarnieri, 2012). On the other side of the balance sheet, discoveries of plentiful crude oil led to falling gasoline prices while technological improvements to ICE vehicles improved their reliability and comfort, whereas further enhancements to battery technology to enhance EV range were not forthcoming. Guarnieri places particular emphasis on a specific feature during the 1910s—ironically an ancillary electrical device—the electric starter, which replaced the manual starting procedure of hand-cranking.

Another contextual factor was the improvement of interurban roads. During the second half of the 19th century, the railways offered by far the most efficient means of interurban freight and passenger movement and demand for long-distance road traffic was low and their development and maintenance only a local, not national, concern or responsibility (Plowden, 1971). The passenger car and the freight delivery truck were primarily local, urban vehicles; a situation which suited the capabilities, and in particular the range, of the BE vehicle. As road vehicle performance improved, however, the demand for paving highway networks to ease the passage of pneumatic tires, rather than surfaces which facilitated horses' hooves, strengthened (Plowden, 1971) and from the 1920s countries such as Italy, the United States and Germany pioneered high-speed, high-capacity highways, for long-range traffic, with access restricted to motor vehicles, a technology which would be a growing source of competition with the railways.

The rise of Fordist mass production methods from 1908 seems only to have enhanced the affordability of the ICE vehicle, and set in train intense technological development of the automotive industry around the ICE to become one of the most significant global industrial sectors and spawning a coevolution of society and car known variously as car culture, automobility (Urry, 2004), or car dependence (Mattioli et al., 2020). In a similar way to which tramways and suburban railways had facilitated urbanization around "transit corridors," ICE road vehicles encouraged suburbanization and commuter dormitory towns; development forms which locked-in dependence on medium-range motor transport by road. EVs "retreated" to niches typically characterized by specific environments and duty cycles, such as the before-dawn, door-to-door, stop-start, local deliveries of milk traditional in British residential neighborhoods, for which quiet operation was essential.

Hence, the ICE, and private car in particular, came to dominate the regime of mobility, after 1920 even influencing the wider landscape. While several factors favored the ICE in the road sector, a key competitive disadvantage for EM was that vehicles in motion need a mobile power source. Like solid coal burnt in an external combustion engine, or petroleum-derived liquid fuels exploded in an ICE, electricity is an energy transfer "vector." However, unlike coal or gasoline, its storage needs are technologically complex and their development has lagged that of the other facets of the electric powertrain, such as the electric motor. Davidson's early demonstrations involved battery power from expensive non-rechargeable batteries (Day and McNeil, 1996). Rechargeable batteries followed, but their development has represented a struggle for greater "energy density": to increase the amount of energy that can be carried for the weight and size of the battery, in order to increase the range that BE vehicles can travel between charges. The following section considers technical solutions which have emerged to address the storage problem and the niches they created.

Innovation and Diversification to Circumvent the Storage Deficit

Given some clear advantages with electrification - the absence of exhaust emissions, low noise, and the simplicity and reliability of electric motor design - it was natural that solutions would be sought to combine electric traction with an alternative to complete reliance on battery storage.

The first of these solutions was to provide an intermittent or permanent electrical contact between the mobile vehicle and its fixed infrastructure. Werner von Siemens demonstrated the first externally-alimented electric locomotive in 1879. By this time, steam traction had spread across the industrializing world, but a range of technologies for tramways and railways followed, initially relying on electrified rails, later mostly deploying overhead pantographs. While underground steam railways powered by coke or smokeless coal had been introduced in London from the 1860s, the smoke-free basis of electric traction made it a clear preference for this form of railway, with the first electric line in London opening in 1890. Electrification would also become the power source of choice for surface suburban commuter rail markets, where it has been preferred for technical performance in a frequent-stop service regime as well as its environmental credentials. Similarly, whereas steam-powered street trams had occasionally been deployed, it was the electric tram and street car networks that replaced the horse tram and enabled the late 19th and early 20th century urban expansions.

Figure 1 Rail passenger-km by electric and diesel-powered services for selected years. *Source: Based on data from the International Energy Agency (IEA) (2019). The future of rail: opportunities for energy and the environment, IEA, www.iea.org/statistics. All rights reserved; as modified by the author.*

The first interurban electrified line was opened in Italy in 1902. By 2016, 70% of rail passenger-km globally were on electric services (Fig. 1), although the share for freight ton-km was closer to 50% and the extent of adoption of electrification for long-distance railways shows a much more varied position globally, depending on national context and policy. In some countries, such as the United States and United Kingdom, with domestic coal and oil reserves and powerful associated industries, electrification had low priority, with the high capital investment in pantograph infrastructure judged not to be worth the long-term benefits in terms of energy savings and maintenance costs, and in those jurisdictions steam was mainly replaced by diesel. In Japan and much of continental Europe, in contrast, where there has been greater dependence on fossil fuel imports, and sometimes significant domestic nuclear or hydroelectric generation, electric power is near-universal.

Some states without full electrification are now seeking to retrofit as part of their decarbonization plans, and some form of EM will be the motive power of choice for all new-line rail investments. Indeed, since the 1960s the development of high-speed rail, defined as lines achieving maximum speeds in excess of 225 km h^{-1} , is with few exceptions (Such as the UK's "High Speed Train" developed in the 1970s to run on hybrid diesel-electric power) a project intimately related to advances in the electronics of power supply and control. This relationship has been further cemented by the realization of a limited number of "maglev" guided transport systems, such as the Shanghai-Shanghai Airport shuttle in China, which exploit the long-established principles of the electric linear induction motor. If realized, Elon Musk's "Hyperloop" would place maglev systems in partial-vacuum tubes to reduce air resistance in order to reach theoretical speeds of 1200 km h^{-1} , creating competition with air travel.

Away from railways there are few examples of electric supply via fixed contact, and they share a "corridor"-basis, often have exclusive alignments, and have networks of modest total length and complexity. They include urban "trolleybuses" operating in a similar service niche to trams, but making use of roads rather than rails, and a few very rare circumstances of ferry or tug operations on confined water passages such as canals. However, there is renewed interest in the last few years in electrifying roadway infrastructure. Experiments have taken place with the powering of heavy freight vehicles via pantograph on a highway in Sweden (Mendelsohn, 2016), which amounts to the transfer of a tested rail technology, as well as more radical proposals for the inductive charging of EVs on the move (Jang, 2018), although significant technical and capacity barriers would need to be addressed to realize such a system at wide scale.

The second approach to the problem is to provide a source of onboard power generation to avoid the need for energy storage. The highest profile application has been the use of diesel ICEs or gas turbines in railway locomotives to produce electricity for traction. The most extreme, but also one of the most long-standing solutions has been, uniquely in the marine sector, applications of nuclear reactor technology, requiring the substitution of the radioactive fuel rods only a few times in a vessel's lifespan. The submarine grew in significance as a weapon during the 20th century, with its importance fundamentally linked to it being hard to detect while underwater. However, while a snorkel device can be used to supply air to and extract exhaust gases from an ICE for immediate subsurface operation, this is not practical for deep immersion. Hence, the limitations of battery power on submerged range led, from 1955, to the application of nuclear power generation. Subsequently the technology was extended to a small number of large oceangoing electric surface vessels, mainly warships, but with a handful of civilian "icebreakers" developed for use in the Arctic by the Soviet, then Russian, states.

A far more affordable and applicable mobile power generation source than nuclear technology is the hydrogen fuel cell (FC), producing electricity by electrolysis rather than fission, although requiring frequent refueling with a source of hydrogen. FCs have a

technical heritage to rival batteries but their first high-profile application was in providing electrical power onboard spacecraft. Experimentation into terrestrial transport applications mainly emerged in the current century, with a number of limited-production fuel-cell cars having been demonstrated or offered to a small number of consumers under lease arrangements. The first model with a significant production run and being available to purchase outright (at least in some markets) was the Toyota Mirai, from 2014, offered at a premium over ICE vehicles similar to that of BE vehicles. By 2020, sales amounted to around 5000 globally. The advantage of the FC EV is that it largely replicates the ICE vehicle user-experience; the refuel time of hydrogen pressured to 70 MPa is around 4 min and gives a range of 500 km. However, the sales figures reflect the limited availability of hydrogen refueling infrastructure globally; an infrastructure the development of which is in competition with BEV charging facilities, and in second place for investment funds.

The FC solution is also dependent on the provisioning of carbon-neutral hydrogen. While in principle this can be achieved using renewable electricity to electrolyze water, established industrial hydrogen production is based on reforming natural gas, producing carbon dioxide in the process. Efficiency losses occur in the production process, and also from compressing hydrogen to facilitate the transport of practical quantities. Advances in the storage of hydrogen in nanoporous membranes could reduce both compression costs and the need to carry hydrogen in heavy tanks (Noguera-Díaz et al., 2016), but for now these practical factors combined with lingering concerns about the safety of hydrogen mean battery technology remains the more attractive option for most light road vehicle applications.

However, if BE technology is a constraint for light-duty vehicles, it is a far greater one for heavy-duty vehicles such as buses and trucks, where the weight of the batteries necessary to provide for even short-range operation cuts into the payload and comes at very high cost. This has not prevented over half a million EV buses entering service in China, but only a few thousand in total elsewhere in the world (IEA, 2020), sometimes with in-service top-up charging at stops and termini. Indeed, the case for FCs remains potentially strong for niches which involve fleet operation from designated depots, and particularly for long-haul heavy goods vehicles. FC applications for rail vehicles are also emerging where permanent way electrification is not financially or technically viable, and are under development even for aircraft, where weight is particularly critical, and there are safety concerns about the lithium batteries. Here, electrification is not only a pathway to decarbonization, but could also avoid the release of water vapor at high altitude, as this is an additional source of the “greenhouse” effect.

The third approach has been to adopt hybrid technologies whereby a vehicle draws upon a battery for part of its energy needs, and this is combined, either in concert or in alternation with, another power source. In 1997, recognizing that battery technology was not commercially viable for a saloon-sized, high-specification vehicle, Toyota launched the first mass-produced hybrid-electric car, the Prius, using electric power to replace or assist the most inefficient operating phases of the ICE, that is, running at slow speed, accelerating and decelerating. Initially hybrid EVs ultimately obtained all their energy from the liquid fuel and had negligible zero-emissions operation, but by 2020 most hybrids had batteries which could be pre-charged from the electric grid. By the time, the fifth-generation Prius model was launched it had a battery-only range of 40 km and an increasing share of primarily ICE vehicles had some hybrid capability. The Toyota Mirai is in fact an FC-BEV hybrid.

However, while hybridization has been a useful transitional technology, and will remain so in locations without adequate BE infrastructure, it comes with the higher cost and vehicle weight of duplicating the powertrain, and increases complexity over the ICE, rather than reducing it as a pure EV does. There are also concerns about the extent to which consumers actually make use of the pre-charging capability of “plug-in” hybrids (PH) or mainly run them on fossil liquid fuels. Hence, for many commentators concerned with road transport, hybrid technology, and for that matter FCs or electrifying the infrastructure, remain less effective and deliverable solutions than enhancing BE performance. The following section considers the “emergence of a trajectory of electric mobility” (Dijk et al., 2013: 135) led by BE solutions, focusing on the electric car.

The Re-Emergence and Rise of the Battery-Electric Vehicle

Similarly to the way in which the original electric vehicle technology shadowed the rise of electrical science, the re-emergence of the EV from the 1990s reflected advances in electronics including semiconductors and microprocessors used in power electronics from the 1950s and the lithium-ion battery in the 1980s, which increased capabilities and performance. The first half of the 1990s also brought political salience to the matter of urban air pollution from ICEs, and by the end of the decade tackling “climate change” was a dominant idea in policy rhetoric, if not matched in intensity by policy action.

However, while battery car performance was improved in this early period of the re-emergence, the available vehicles were not “substitute good” competitors for ICEs. Consumers could essentially choose between small production-run electric adaptations of ICE models, mostly vans intended for urban delivery use, or microcars such as the Reva/G-Wiz; a spartan design with a range of 80 km and maximum speed of 80 km h⁻¹, and not legally defined as a car in some jurisdictions. A breakthrough for the BE vehicle came in 2010, when Nissan launched its Leaf model; the first purpose-designed, battery-only, compact car from a mainstream manufacturer and intended for mass production. From an initial specification providing a range of around 120 km, by 2020 the capability of second-generation vehicles was up to 270 km and cumulative sales were reaching half-a-million cars.

While Japan has been an important locus of the development and commercialization of EV technologies, certain states in the United States, notably California, have also been an important market both for development and consumption, where the adoption of noxious emissions controls gave an important regulatory emphasis to low and zero-emission vehicle sales. As well as being important as a launch-market for vehicles such as the Prius and Leaf, California has seen the founding of Tesla, an exceptional case of

a private-sector start-up managing to break into a crowded automotive sector to become a significant “disrupter” of its business model.

Formed in just 2003, Tesla had its limited-production Roadster derived from an existing ICE model available around the same time as the Leaf, followed by its fully purpose-designed Model S in 2012. On most metrics (market capitalization, EV production) Tesla is the most successful EV producer to date, and in 2020 was the most valuable automotive company of all power-types, although had only recently reached consistent profitability. Tesla’s disruptive credentials arise conceptually from confounding the belief that it was impossible for a start-up to break into an expensive and competitive industry, and in technical terms from being a vertically-integrated manufacturer *and* retailer. Alongside these were radical design choices such as the use of carbon-fiber polymer bodies and a new approach to battery construction achieving higher energy-density. From the consumer perspective, product design and marketing choices emphasized performance and significant battery range (with even the standard Model S having a theoretical range of 335 km), despite the implications for pricing. Combined with features such as “automation-ready” control systems and the establishment of a bespoke network of exclusive recharging facilities, much higher speed than the typical public-sector backed facilities, the result has been the development of a premium brand with strong social desirability and customer loyalty, even if the commercial strategy is to target future models to the more affordable mainstream as technology costs fall.

Alongside Tesla and the Japanese manufacturers, China has emerged as a third force in EV production, notably through manufacturers such as BYD Auto, which has specialized on EV production ranging from city cars through to trucks. China has also become the largest market for EVs in the world. Fig. 2 summaries the global stock of electrified cars in 2019. It should be noted, however, that despite a recent 40% year-on-year growth rate, plug-in vehicles represent just 1% of the global fleet.

Although the sales of Chinese and South Korean EVs had focused on price competition and had been directed towards the emerging and developing economies, imports to Europe were of growing significance from 2020. In Europe itself, industry resistance to change combined with a policy focus on reducing carbon emissions through the adoption of more energy-intensive diesel ICEs has left the continent’s manufacturers seeking to catch up, even if a crisis in air quality, ironically exacerbated by a “dieselization” policy that limited EV development, is now stimulating demand.

The passenger car and the light commercial vehicle are the critical vehicles in transport policy in the advanced industrialized states. Even in countries associated with cycling, such as The Netherlands, the modal share of travel measured in passenger-km is dominated to the order of 80% by cars (Parkhurst et al., 2012). And linked with changes including the rise of digital commerce, light goods traffic has shown particularly sharp increases. Nonetheless, electrification is also associated with the rise of new, or re-envisioned modes of transport, facilitated by the enhanced power-to-weight ratio of improved and affordable lithium-ion batteries and digital control technologies which render EV technologies efficient and can provide extra value via consumer interfaces, such as theft warning and optimization advice.

Figure 2 Global stock of BE and PH cars in 2019 (millions). Source: Based on data from IEA (2020). Global EV Outlook 2020, IEA, www.iea.org/statistics. All rights reserved; as modified by the author.

One successful area of application of electrification has been in respect of existing two-wheeled vehicles. Bicycles and motorcycles, particularly the lower-powered urban “mopeds” and scooters, have typically had a modest speed of operation over relative short distances. Combined with lithium battery technology, and low vehicle weight compared to cars, these EVs can easily achieve their duty-cycles, while the batteries can be detached from the vehicle for charging at a standard power outlet indoors, or swapping for charged units at a service center. (An attempt was made by US–Israeli firm “Better Place” to establish a similar battery-swap scheme for passenger cars. Pilots began in 2012 in Israel and Denmark but the business model did not prove viable due to the scale of investment required to establish a swap network at wide geographical scale and the difficulty of attracting car manufacturers willing to accept battery standardisation to the specification of a small start-up (Gunther, 2013)).

Motorcycles constitute a significant share—up to two-thirds—of vehicle traffic in some Asian cities so substituting that vehicle class with EVs offers significant air and noise pollution reduction benefits as well as offering the potential for decarbonization. The electric bicycle, instead, is usually a hybrid of human and electric-power and has great potential to open up the mode of cycling for people for who find unassisted cycle journeys too hard work, or too long, but at the same time encourages cycling as a form of physical exercise, for transportation or leisure. The latter is an important non-transport policy consideration given the crisis in the wealthy countries around the “diseases of affluence” and inactivity, such as obesity, heart disease and diabetes. Even in countries in which cycling is an important transport mode, such as the Netherlands, e-bike sales now have significant market share, as a means of cycling longer journeys.

A second area of application is in respect of “personal” mobility or “micromobility”. It has long been argued that the passenger car is over-specified for most journeys, made by sole travelers for short distances, and that smaller single-person vehicles, typically electrically powered, could offer a more efficient alternative. Indeed, light-weighting is a particularly effective strategy in the case of EM, as vehicle weight has a greater influence on efficiency than for ICE vehicles, for which engine power is more important (Weiss et al., 2020). However, high-profile failures (such as the Sinclair C5) and highly-qualified successes (the Segway) underline that the established two-wheel vehicle options already offer an alternative to the private car that is hard to improve on for many traveler-journey options. Nonetheless, the recent emergence of the “e-scooter” (confusingly the same term scooter has been applied to rather different technologies; in this case is meant the vehicle with two small in-line wheels and a standing platform with vertical handlebar) is deserving of attention. Facilitated by automated short-term hire systems, the vehicles have become a feature of the central areas of many major cities in recent years, where they offer an alternative to walking and other transport modes for short journeys. While promoted for their energy efficiency compared to other powered modes, concerns have emerged about their safe use either when mixing with pedestrians or road traffic, the longevity of the vehicles when offered in public sharing schemes, and problems with inconsiderate parking at the end of hire. However, given their lower capital cost compared with e-cycles and greater ease of carriage and storage, e-scooters have strong advocates and the mode benefitted from the emphasis placed on personal rather than collective mobility triggered by the Covid-19 pandemic outbreak in 2020.

Freight equivalents of personal mobility have also been beneficiaries of electrification, as well as automation technologies. The need for zero-emissions local freight has boosted interest in cargo-bikes in various formats in recent years, and three-quarters of these purchased in Europe now have electric assistance (cyclelogistics.eu, 2020). (The same technology is also highly appropriate for cycle taxis or rickshaws, where “pullers” in low average income states often suffer from excessively physically demanding work.) However, due to the labor-intensity of urban deliveries, combined with consignment sizes which are often small, the company Starship is developing delivery-bot services, using a secure wheeled box with a maximum payload of around 50 kg and a maximum range of 6 km, achieved at walking speed and using automated navigation and control systems.

A third area of innovation is essentially to take these surface EV developments to the skies, in the form of “urban aviation,” to take advantage of the vertical dimension of space as a means to reduce congestion. According to this vision, short-range, low-altitude, light BE aircraft, typically powered by multiple rotors, could offer both passenger and freight services. Remote-controlled “drone” operation is long-established in military applications and has seen diversification into specific applications such as emergency medical logistics in rural areas. Transferring this technology to the urban consumer sphere, and potentially automating its operation, raises a number of safety, privacy, noise, and regulatory concerns, including the fundamental issue of overflight rights, all of which remain to be solved. Additionally, the energy efficiency and commercial viability of such services remains to be proven.

A Sustainable Mobility Policy Perspective on Electric Mobility

So far in the article, EM has been established as a bundle of transport modes and services that many commentators hope will transform the impact of our mobility on the environment while ensuring high accessibility for all. It has been seen how ingenious technological development is enabling the possibility of motive power which is efficient and emissions-free at the point of use for the entire global transport system. But a number of questions remain to be answered and challenges overcome before EM can be confirmed as being the core technology for a more sustainable future, and indeed one that contributes to a transport regime change.

The first of these concerns just how much more efficient EM will be compared to existing options? This is important as decarbonization must involve two related changes in order to be deliverable in time to meet global climate management needs: all energy must be sourced from carbon neutral sources, and to make that achievable in a context of growing populations and economies, energy must be used more sparingly. For EVs the answer to this question is reasonably clear in theoretical terms: based on current technologies a pure EV car is around 60%–66% more efficient than its ICE equivalent in use (UK Department for Transport, 2018), with those benefits arising, despite relatively heavy like-for-like weight, from the relative efficiency of the motor,

the elimination of “idling” and features such as the regeneration of energy under braking. But even with this significant benefit, for a wealthy, highly-industrialized economy the additional demand on the electric supply infrastructure will be very significant; in the case of the UK completely electrifying the transport system will require a doubling in demand (Eyre and Killip, 2019), as well as major challenges to manage peaking in demand across the key sectors: transport, domestic, and industrial. Here “smartgrid” techniques are emerging to ensure BE vehicles charge at periods of low domestic and industrial demand, with power potentially being offered back to the grid from individual vehicle batteries at peak times if the charge state is higher than necessary for expected immediate travel needs. Enthusiastic, expert consumers can already take part in such a market, but it remains to be seen how far the typical consumer is willing and able either to plan needs in a tariff-led system or simply leave it to the algorithms to decide.

The key uncertainty regarding the other part of the efficiency-neutrality tandem concerns the significant variation globally in the dependence of regions and nation states on high-carbon electricity. Including the emissions which derive from producing an ICE vehicle or an EV and disposing of it at the end of its life, and assuming the current global mix of fuels used in electricity generation, then the whole lifecycle greenhouse gas (GHG) impact of an EV is around 70% of an ICE equivalent (Elgowainy et al., 2020). A 30% saving is certainly worth having but is not in itself a transformative change. Shifting to carbon-neutral electricity could improve that saving to at least 60% of an ICE equivalent (assuming the ICE continues to operate on fossil fuel). EV technology is not the only “vehicle-fuel pathway,” which can theoretically deliver this magnitude of reduction, but it is currently the most deliverable option for replacing the fossil-fuel ICE regime, and within the options for electrification, if the challenge of providing sufficient battery-electric recharging infrastructure is significant, at least a well-developed electric supply grid exists, whereas the supply of hydrogen for FCs requires a refueling system to be provided almost from nothing.

Even a 60% saving in GHG emissions must be qualified by forecasts globally for very significant expansions in both vehicle fleets and distance travelled, which will to some extent offset the benefits of electrification (Greene and Parkhurst, 2017; Morgan, 2020). Indeed, EVs themselves are a factor predicted to increase traffic for both economic and psychological reasons. EVs are relatively expensive to buy but relatively cheap to use. The high investment in an EV is likely to “lock-in” owners to car use, while the negative elasticity of travel demand with respect to cost of car use implies traffic growth due both to their efficiency and the low cost of (often low-tax) electricity. “Rebound effects” of this nature can be expected to be further encouraged by EVs being perceived as an environmentally-benign technology; arguments in favor of public transport or active travel may carry less weight with the owners of EVs.

Even if there is high global success in decarbonizing electricity for motive power, emissions from vehicle provisioning will remain important (Morgan, 2020). For these reasons, it is argued that decarbonization must not become overly-reliant on technological substitution, and that an evolving sociotechnical regime of sustainable mobility should also involve changes in individual behaviors and social practices to moderate the rising demand for vehicles and travel. But herein lies a political and commercial conundrum which undermines the principles of the smart mobility revolution. Purchasers of “early modern” BE cars understood they were making a lifestyle change, often for overt reasons of environmental politics. They would adopt energy-conserving driving styles to maximize battery range and did not expect the EV to provide for all the journeys they expected to make, relying instead on the EV as part a diverse multimodal “mobility style.” Precisely in order to widen and deepen the appeal of EVs, though, significant research and development has been invested in both larger and more energy intense battery packs and faster charging facilities both to reduce the “range anxiety” of users and facilitate long-range journeys through 20-min recharging capability. As well as providing business-as-usual for the consumer, such a strategy preserves as much of the 20th century business model of the ICE automotive industry as possible. Alongside extended range, the “business-as-near-usual” powertrain continues to promote the “owner-driver” model of car use as well as perpetuating the equipping of private cars with performance capabilities in terms of acceleration and maximum speed which exceed practical requirements and most legal constraints. Although Tesla seeks to emphasize differences in design and production, it is through this same overarching business model that Tesla has become the most successful producer of electric cars globally to date.

Greater range also removes the incentive for energy-efficient driving; indeed, the relatively high torque of electric motors may result in a rebound effect whereby part of the efficiency gain is reinvested in more “sporting” driving. As exhaust emissions are reduced, non-exhaust sources of pollution become relatively more important, but as vehicle fleets grow in number and weight they also increase in absolute terms (Air Quality Expert Group, 2019). A more aggressive driving style also accelerates the rate of tire and friction brake wear that arises from EVs as well as ICE vehicles, in turn increasing the significant contribution of automotive sources of particulates and microplastics to environmental pollution (Evangelidou et al., 2020).

Another facet of policies to promote EVs as a direct substitute for ICE technology is that governments around the world have introduced fiscal and regulatory incentives to reduce the perceived barriers to becoming an owner-driver of a BE. Norway is the prime example (Figenbaum, 2017), where 42% of passenger cars newly registered in 2019 were zero-emission, and another 26% hybrids (Norwegian Road Traffic Information Council, 2020). The range of incentives applied around the globe has variously included grants towards the vehicle purchase price; income-related tax incentives; grants for home, workplace, and public-domain charging; exemptions from tolls, emissions charges, and parking fees; even the permission to use bus lanes, despite the fact congestion caused by an EV is just as delaying as that caused by an ICE vehicle, and that the decarbonization case for public transport solutions is strong considering both emissions in use (Logan et al., 2020) and across the lifecycle (Elmers et al., 2020). However, rather than re-envisioning the passenger car as just one modal contributor to a “Mobility-as-a-Service” environment, with vehicles hired for specific trips, and even ride-shared with strangers (Parkhurst and Seedhouse, 2019), providing subsidies and incentives for EV use continues a policy tradition of not expecting private road users to meet the costs they externalize, and prioritizes supporting volume of production in the automotive sector. Looking to a potential future with vehicles which are automated as well as electric, a similar

prospect beckons: while it is conceivable that these could be an efficiently-used collective fleet, a more plausible outcome is that market forces and social practices will perpetuate overwhelming dependence on the private car. Indeed, there is already evidence that the innovative niches of more sustainable mobility, such as shared e-bikes, will be short-lived (Lin et al., 2018).

In summary, the article has reviewed how electric propulsion emerged in the first half of the 19th century, and by the latter part was serving specific niches in the transport sector, some of them important enablers of urbanization. EM niches have been characterized by particular operating environments, or specific kinds of delivery service, or duties in industrial sites, or in submarines, or where the conditions have been particularly suited to major electric infrastructure provision, notably on the railways. Recently, a resurgence in EM has also supported the emergence of entirely new modal niches, such as personal transporters, and adapted niches, such as the case of civilian drone applications close to the functions of helicopters. However, much of the growing emphasis placed on EM represents technology substitution; substitution into a regime, that is to say a set of social, spatial, and industrial-economic conditions, which has coevolved to optimize synchronicity with other technologies, mainly the liquid-fueled ICE. Hence, multiple barriers need to be overcome both through developing the technology, but also, it must be argued, reshaping the regime.

To conclude, it is just possible that further rounds of technological innovation and infrastructure investment could result in effectively limitless carbon-neutral energy. Similarly, this plentiful energy might be combined with much enhanced storage, for example if long-life, stable and recyclable metal-air batteries can be achieved then the theoretical energy density is ten times higher than current lithium-ion batteries (Imanishi and Yamamoto, 2019; Liu et al., 2017), and concerns about the supply of sufficient critical raw materials are resolved (Narins, 2017). However, the precautionary principle urges that we cannot risk that these circumstances do not prevail. We need to use our motorized vehicle fleets more efficiently (higher load-factor per km), more intensively (fewer vehicles per capita), more sparingly (greater modal share to human-powered transport) and over shorter distances (spatial and economic planning to reduce the need to move people and goods), as well as electrifying our mobility.

Biography

Dr Graham Parkhurst is Professor of Sustainable Mobility and Director of the Centre for Transport & Society at UWE Bristol. He holds degrees in Psychology and Philosophy (BA University of Warwick), Human Biology (MSc University of Oxford) and Transport Geography (DPhil University of Oxford), and has researched and taught academic transport and mobility studies since 1991. Past research interests include urban and subregional transport policy, modal interchange policy, air quality policy, mobility of the ageing population, transport policy instruments and the evaluation of urban transport policy implementations (specific infrastructure interventions, mobility services, and vehicle technologies). His current research is examining the wider implications of the trends to greater automation, electrification, flexibility, and use of digital technologies in the transport sector, taking a critical lens to the discourse and practices of "smart mobility" and "smart cities", through projects such as *Driverless Futures?* (Economic and Social Research Council) and *Replicate* (European Commission). Graham has provided social and behavioral research contributions in respect of UK-Government-funded (Innovate UK) research consortia examining connected and automated vehicles (*Venturer*, *Flourish*, *CAPRI*, *MultiCAV*, *CAVForth*) and flexible collective transport solutions (*Mobility on Demand Laboratory Environment*). Graham also teaches Transport Policy at Masters' level and is a Fellow of the Royal Geographical Society.

The Governance Turn in Transport Policy

This chapter aims to describe the development of governance in transport policy studies and show central aspects that have emerged within this field. The paper draws from studies in transport as well as general policy theories on policy making and governance.

Governance research in the transport sector can be traced back to the privatization reforms that were introduced to this sector in the 1980s. During this period, many countries gradually introduced different types of deregulation elements. The regulatory reforms initiated in the United Kingdom, where competition was introduced into the public transport sector in London in 1984 and the rest of the country in 1985 (Gwilliam, 2008), can be seen as the starting point of changes in policy making within the transport sector. In this discussion, the new role of the government was set in focus; it emphasized its role in deregulating the sector or withholding authority in terms of having a strategic position within contracting regimes (Beesley & Glaister, 1985; Gwilliam et al., 1985). Hence, in the 1980s transport policy studies were strongly focused on aspects related to market regulation and competition (Gwilliam, 2008). In the 1990s, studies discussing the forms and mechanisms of competition emerged, linking organizational reforms to output (Hensher & Wallis, 2005; Gwilliam, 2008). In parallel with privatization reforms, there was an increased focus on sustainable transport policies, which was driven by both international organizations, such as the EU, and bottom-up initiatives. In these policies, coordination among actors and collaborative practices were brought up as part of the solution. From the 2000s, there has been a stronger emphasis on governance aspects within the sector, trying to capture the increasingly fragmented nature of transport policy.

Hence, from the 1980s the traditional “command-and-control” function of the state (=government) has increasingly given way to a more facilitating function (=governance). This means that the state assumes the role of facilitating agent by letting nongovernmental actors into the process while taking a more removed, coordinating, and steering role (Joss, 2015, p. 63). In short, governance scholars are concerned with the “relational organization” that the government has taken in transport policy, where multiple interdependent actors take part in and influence policy making; they are also concerned with how these relations are designed, and how constituting governance mechanisms, such as trust, contracts, and power structures, among others, are used to influence decision-making processes.

Governance has increasingly gained a position in both academic and wider policy discourses. However, it is worth mentioning that the emphasis on governance among transport scholars is still rather new. Saetren (2005) extensive literature review on policy studies in political science and public administration journals shows that there are limited studies of the transport sector. Transport studies did not even account for 1% of the reviewed studies (Saetren, 2005, p. 571). An analysis by Marsden and Reardon (2017) of 100 papers from the two leading transport policy journals shows that questions of governance are largely ignored in the transport literature (p. 238); only four papers considered the “ends or aims” of policy, that is, the goals, objectives, or settings (p. 244). See a more in-depth discussion in Hansson (2019).

Understanding Transport Governance—Key Features

Central to the governance perspective is the emphasis on the decision-making processes, analyzing how policies are shaped, implemented, and reshaped. Policy making consists of many decisions that, when combined, constitute a policy process. In transport policy, the decisions vary; they may include the choice of technology, the characteristics of the services to be provided, or the sources from which infrastructure and services are to be financed, among others (Gwilliam, 2008). Decisions are taken throughout the policy process (see Figure 1 in Hansson, 2019). This includes decisions that set the policy on the agenda or formulate a policy problem. Decisions also relate to policy adaptation, such as shaping policies from the national level to a local setting. The policy process also consists of decisions about how to implement policies and evaluate their effects, as well as who should be involved in this process. The policy process can be transferred through decisions on multiple governance levels; for example, a policy shaped at the EU level might also be implemented on a local government level within a municipality. In shaping these decisions, various activities take place and are driven by different actor constellations. These can be politicians and officials at various levels of government, as well as other actors, such as interest groups, consultants, private firms, and transport users. Hence, transport policy

Table 1 Two main governance modes, constructed from transport policy literature.

	<i>Policy-situated governance</i>	<i>Tender-based governance</i>
Goal	Innovation, sustainable mobility, and urban development	Service provision
Roles and responsibilities	More loosely defined, includes formal and informal structures	Well-defined, formalized structures (contract hierarchy)
Collaborative relationship	Mutual understanding	Command – execute
Coordinating mechanism	Trust	Contract
Coordinator	Coalition	Public or semi-public actors

Source: Author's own design.

consists of the interrelationships of actors who combine their resources in policy making. The governance perspective tries to identify the role that institutions, structures, and techniques have in managing these processes, as well as the relationships between the multiple actors involved (Joss, 2015, p. 63).

The policy literature differentiates between horizontal, vertical, and multi-level governance. The combination of vertical and horizontal governance is what often is referred to as multi-level governance (Peters, 2001). Vertical governance mark relations between higher and lower levels of government. Horizontal governance represents the relationships between public organizations and nonpublic organisations that are involved in a decision-making process. It is assumed that the public sector is more than a multilevel system in which the lower levels simply implement national policies; instead, lower-level governments, for example, counties and municipalities, hold their own interests as well as their own authority and legitimacy (Hansson & Torsteinsen, 2019). International organizations might also influence national or local policies. For example, countries of the European Union need to negotiate coherently, since these countries must first develop common negotiating positions with their country and then take those positions into discussions with other member nations (Hansson & Nerhagen, 2019; Peters, 2001). Hence, there are intertwined relations and responsibilities among the levels of government and public and private actors; these combined relations constitute multi-level governance networks, which all are part of effecting decisions in one or several phases of the policy process.

The transport policy literature covering aspects of governance is found in multiple transport settings. On one hand, there are studies analyzing policy making on a local level, for example in relation to sustainable transport systems or mobility plans (Tønnesen et al., 2019). There are scholars analyzing the effects of EU policies and how these are shaped and re-shaped in relation to national policies (Hansson, 2019). There are also studies on governance and public transport planning and service provision (Hansson, 2011). There is also a discussion on partnerships that can be related to governance (Sørensen & Longva, 2011). These different thematic threads bring a heterogenic and sometimes conflicting perspective on what governance might be. This paper proposes two main types of governance modes, which have been drawn from the various literature on governance in transport policy: (1) policy-situated governance and (2) tender-based governance (see Table 1). With a base in these two modes, the central features of governance in transport policy will be discussed.

Policy-situated governance is found in several settings, it can be where actor constellations are active in either influencing the content of the policies (in the agenda-setting phase or the policy-formulation phase) or in urban regions where the policies are to be implemented. Policy-situated governance consists of a variety of actors, such as political parties, public officials, enterprises, consultants, and sometimes end users such as citizens. The name “policy-situated governance” relates to a specific policy issue that is to be dealt with, for example, urban development, sustainable mobility, mobility planning, etc.

Tender-based governance is found in the end phases of the policy cycle when policies are transferred into practical implementation. Tender-based governance is sprung from the privatization policies that have a view of governing services from a distance and is highly evident in countries that use competitive tendering in the service provision of public transport.

A central feature of governance is understanding how actors are organized in terms of the responsibilities and resources they have at hand. These roles and responsibilities can be more or less formalized (Paulsson & Isaksson, 2019). Policy-situated governance features more loosely defined roles and responsibilities within the network; for example, a smart mobility process can hold experimental processes in which a broad range of actors are included (Bakker et al., 2014; Docherty et al., 2018). The decision-making processes within these networks hold both formal and informal structures (Hrelja et al., 2017). Tender-based governance holds a more formal and clear division of roles between the actors, based on a contract hierarchy. The contract defines the roles and responsibilities of the private actor(s), while the roles of the public actors are defined by the hierarchy that exists within the public organization's authorities (Hansson & Longva, 2014). The “strategy-tactics-operation framework” (STO), introduced to the transport sector by van de Velde (1999), has also been an influential perspective in this setting. It is a variation of control hierarchy and provides a model for comparing the organizational structures and the development of contractual agreements in different countries. It has allowed a range of issues to be framed and has provided an understanding of various stakeholders' functions, taking either a strategic, tactical, or operational role (van de Velde, 1999; Wong & Hensher, 2018).

Within the transport governance literature, there is a normative view that collaboration between organizations is a critical factor in reaching successful policy implementation. Behind this view is the belief that collaboration might generate new, integrated knowledge and capacities that are not available within individual organizations (Joss, 2015). This rationale is especially evident in policy studies on smart mobility or innovations in urban transport systems, in which shared understanding through the exchange of

knowledge, information, and expertise is seen as central to successful policy implementation (Meyer, et al., 2005). However, studies have also brought forward a more critical perspective on knowledge sharing. Governance constellations hold path dependency traces and new, innovative aspects and knowledge that are difficult to incorporate into existing constellations; this results in a reproduction of old views instead of the shaping of new ones (Hansson, 2019; Hansson & Nerhagen, 2019). In tender-based governance settings, there is also the belief that combining actor resources makes successful policy implementation more likely; however, this is based on a division of competence and labor, in which one part is contracted to execute a service. Within this structure, knowledge exchange/sharing can take place; however, this is defined within the premises of the contract.

In governance structures, actors bring different goals and agendas to the process, making it important to not only clarify roles and responsibilities but also power dimensions and asymmetric relations. There is a power dependency within governance structures, meaning that different actors employ power resources, such as political, economic, and informative resources (Docherty et al., 2018; Hansson, 2011). These resources combined are important for the overall network and are used to negotiate power throughout the process (Hansson, 2011). In tender-based governance, power relations might be easier to control because a contract can include some of these aspects. In policy-situated governance settings, power dimensions are complex and difficult to identify and deal with. Trust is brought forward as a central mechanism in overcoming power dimensions in policy-situated governance settings. Longva and Osland (2007) make the distinction between thin and thick trust. Tender-based relationships can be referred to as “thin trust,” while “thick trust” can be found in complex, intertwined networks that go beyond a competitive tendering regime (Longva & Osland, 2007). However, Stanley and Hensher (2008) stress the importance of also achieving a “trusting partnership” in contract-based settings (negotiated contracts). Various papers have discussed how to create and maintain a trusting partnership. In this setting, it is central that the authority and the provider devote considerable effort to developing the foundations for a trusting relationship during the precontractual phase (Stanley & Hensher, 2008).

There is often an actor constellation that takes on the role of mediating between the various interests and priorities in a governance process; this actor constellation is sometimes called “meta-governor” (Hansson, 2013). The mediating function is helpful in bringing forward actors and gaining a mutual understanding of the issue at hand (Tønnesen et al., 2019). By assuming this coordinating role, the meta-governor may also wield considerable influence over other actors (Hansson, 2013). In tender-based governance settings, the coordinating role is mainly given to public actors, for example, the transport authority (Hansson, 2013); in policy-situated governance, this coordinating role can consist of a more heterogenous constellation (Hrelja et al., 2017). A study by Wikström, et al. (2016) on the electrification of commercial fleets in urban areas also addresses the relevance of a single actor, “policy entrepreneur,” who takes on a coordinating role and pushes policies forward. The concept of “system builders” has also been used for explaining a similar role (Palm & Fallde, 2016).

Future Challenges

Over time, there has been a search for innovative mechanisms for making government work better and serve society better (Peters, 2001, p. 2). This chapter has addressed the governance turn in transport policy and described central features that explain the composition of governance structures. The governance turn in transport policy has been driven by both privatization reforms as well as reforms concerned with how to deal with climate change and promote a more sustainable transport system. These reforms have created a need for enhanced coordination among transport actors and new governance structures. Governance structures affect the transport policy process; they can be found in the early phases of the policy process, such as in the agenda-setting phase, or in the end parts of the policy process, such as when implementing policies.

It should not be given that a governance approach to transport policy delivers more effective or legitimate policy solutions. Practical applications of governance processes in transport policy have pointed out several challenges, underlining what can be a considerable divergence between the normative ideals of governance and actual practice.

Governance, from a policy theory perspective, is still limited within transport studies, even though we have seen an increasing number of scholars taking interest in this field during the last 10 years. As a final point, two aspects that need more research will be put forward.

More collaborative forms of governance require special efforts to ensure transparency and accountability. Governance processes are less transparent when private firms are involved in the early phases of decision making. Compared to the more traditional view of politics, in which politicians are ultimately responsible for decisions while other actors might be involved in the planning or implementation of the decisions, the roles in governance are more diffused (Hansson & Longva, 2014). The aspect of transparent decision making and accountability (“Who was involved in the decision making, and who can be held accountable for actions and the decisions taken?”) is only vaguely addressed in the transport literature, compared to other government sectors. This paper has addressed the notion of contracts and trust, but there is still much work to be done in relation to transparent decision-making and accountability.

Studies have also shown that governance mechanisms designed to reconcile policy goals may in fact intensify tensions between them (Joss, 2015). There is an intense discussion on policy deviance and how to achieve policy integration (Hull, 2008). In this context, it has been argued that governance networks might contribute to policy discrepancy. There are decoupling tendencies, created by governance structures, which mean that some policy elements are separated from the original policy process in order to deal with unwanted conflicts in the network; this results in fragmented policy proposals and difficulties in getting an overview of the proposed effects (Hansson, 2019). Studies have also addressed the problem of parallel policy making (Fallde, 2011). Parallel policy

making reflects “a fundamental lack of integration of sustainable mobility in policies and plans of strategic importance, which hinders effective policy integration” (Isaksson et al., 2017).

The paper has brought forward two governance mode structures constructed from findings in the literature on transport governance and policy. In urban and regional settings, policy-situated governance and tender-based governance might coexist and respond to different policy problems. Combining governance modes with multiple policy-making processes might be central to understanding why policies are not successfully implemented and how conflicting policy goals can be addressed. Studies are welcomed that further develop these governance modes (and perhaps identify more), both in terms of how they work separately as well as how they might conflict with or enhance parallel policy making.

Introduction

This chapter is concerned with the processes by which transport policy measures are transferred to specific urban locations from elsewhere. Following this introduction, Section 2 provides overviews (firstly on a global level and then on an EU level) of guidelines describing generic *good practice* concerning policy measures, which provide an important mechanism for achieving the first step in the transfer process, which is to start the circulation of information. Such guidelines, which are typically easily available for free on the Internet, have an intended audience of decision-makers and informed citizens/stakeholders. They are generally visually attractive, avoid using overly technical/academic language, and usually provide particular case studies illustrating the good practice principles being advocated. Inevitably, though, such *broadcasting* of good practice can pay little attention to the specific needs and contexts of cities that might implement the measures and so cannot reflect upon the full transfer process, except in a relatively simplistic fashion. Furthermore, in order to maximize their readership, they inevitably describe policy measures in a simplified idealized way, leaving out (or at least playing down) some of the “messier” complex details about their implementation, thus leading to an *information gap*. The job of filling this gap has been taken on by academic researchers, whose concepts and research results provide the subject matter for the remainder of the chapter.

A key watershed in the development of academic research on policy transfer in transport studies was provided by the publication of a special issue in the journal *Transport Policy* on “Transferability of urban transport policy” (Ison et al., 2011), which provided a comprehensive snapshot of different approaches to researching the subject at the time. These papers are discussed in Section 3, which also contains information about a parallel stream of research that saw the transfer process in terms of a *policy mobility* conceptual framework. Although not specifically concerned with transport policy, it was to play an important role, conceptually and methodologically, in influencing subsequent studies on transport policy transfer.

Section 4 provides an overview of academic research on urban transport policy transfer since 2011. Such research has taken profound directions since 2011: although the questions might be the same (or at least similar) the analysis goes deeper. Section 5 concludes the chapter with two suggestions for further research.

Good Practice Guidelines

Global Level

There are currently a number of international NGOs providing good practice guidelines on urban transport, including: the Institute for Transportation and Development Policy (ITDP)^a; the World Resources Institute – EMBARQ^b; and GIZ’s Sustainable Urban Transport Project (SUTP)^c. The roles of these NGOs are described by Sosa López and Montero (2018) as:

“politically complex: sometimes they collaborate with government officials, and in other occasions, they become their most forceful opponent. They alternately identify themselves as civil society groups that represent citizens, and other times they rely on their connections with global philanthropy and international development banks to present themselves as transport experts.” (p138)

While providing information on a full range of urban transport measures, these NGOs are particularly associated with the promotion of Bus Rapid Transit (BRT) (Sengers and Raven, 2015; Paget-Seekins, 2015). In particular, ITDP produces an extensive

^a <https://www.itdp.org/>

^b <https://www.wri.org/tags/embarq>

^c <https://www.sutp.org/en/>

online BRT Planning Guide^d and the BRT Standard (ITDP, 2016). The latter provides a detailed point-based scoring system which enables BRT planners to “certify” their BRT corridor as “basic BRT, bronze, silver, or gold,” thus placing the BRT corridor “within the hierarchy of international best practices.” While such an approach is no doubt useful in providing much technical information that needs to be taken into account when planning a BRT, the hierarchical scoring system risks being over-prescriptive, particularly as it is unable to take into account local contextual factors. From a transferability point of view, it is thus problematic.

EU Level

The European Union (EU) is of particular interest with respect to transport policy transferability, due to the large number of cross-national applied transport research projects that have been funded by the European Commission (EC) over the past 30 years (Rommerts, 2012, TRIP, 2014 and 2016). Inevitably, questions are raised in such projects about cross-national transferability. A recent product of EU applied research of particular relevance to this chapter is the second edition of the “Guidelines for Developing and Implementing a Sustainable Urban Mobility Plan [SUMP]” (Rupprecht Consult, 2019), which includes a step entitled “Measure Selection”. Although the guidelines are prescriptive in terms of process, they are less prescriptive, in comparison with the BRT Standard, with respect to the actual measures that might be adopted in any particular location. These guidelines, along with many other associated guidelines about particular aspects of the SUMP process (such as how they might be applied in different sizes of city) are available from the European Local Transport Information Service (ELTIS) website^e, which also has a large store of one-page descriptions of case studies (mainly from the EU but also from other parts of the world).

May (2015) describes the background for the development for the first edition of the SUMP Guidelines, listing some of the EU research projects that directly or indirectly made contributions. These include an early contribution by the PROSPECTS project, which produced the Decision Makers’ Guidebook (DMG) (May, 2005). The DMG was intentionally designed to be reader-friendly, using humorous cartoons to illustrate various aspects of the policy-making process, including the transfer of policy measures (shown in Box 1). As can be seen, the DMG emphasised that decisions about appropriate policy measures are dependent upon local context: they cannot simply be “imposed from above.”

The recommendation of the DMG to record experience (see Box 1) has been facilitated by the existence of the large number of EU research projects mentioned earlier. However, the resulting quantity of available information directly leads to practical questions as to how any decision-maker might make use of it in the policy transfer process. Macário and Marques (2008) developed a “10 Step” scheme, as illustrated in Figure 1, based upon their experience in EU research projects. A simplified “light” version of this scheme, for use in urban locations with less resources for carrying out a full transferability analysis, is described by Timms (2014). Whether “heavy” or “light,” all such ex-ante transferability analyses require an assessment of potential measures (Step 8 in Figure 1), leading to key context-specific questions such as:

- what is the role of public/stakeholder participation?;
- are the measures contested by different groups?;
- what objectives are the measures intended to achieve? (and from whose perspective(s)?);
- who is supplying the information from other locations? (and what are their motivations?);
- is the information about other locations “reliable”? (and from whose perspective(s)?);
- is the experience of some locations more influential than that from other places (and why?);
- which technical tools (if any) might be used in analyzing transferability?

All these questions lead to the need to understand policy transfer as more than just “broadcasting” good practice guidelines, and provide (some of the) questions to be tackled by academic researchers, as discussed in the next two sections.

A Snapshot of the State-of-the-Art in Research on Policy Transfer in 2011

As mentioned in the introduction to this chapter, a key moment in the development of academic research on policy transfer in transport studies was provided by the publication of a special issue in the journal *Transport Policy* on “Transferability of urban transport policy” (Ison et al., 2011). Of the six papers in the special issue, Marsden and Stead (2011) provided a review of the state-of-the-art on concepts and evidence, while the other five papers described case studies covering different aspects of the transfer process (Marsden et al., 2011; Timms, 2011; Bray et al., 2011; Rye et al., 2011; Attard and Enoch, 2011). In order to provide a consistent approach, the authors of all six papers were asked to use a common framework made up of questions derived from Dolowitz and Marsh (2000): Why transfer?; Who is involved?; What is transferred?; From where?; What is the degree of transfer?; What are the constraints?; How is transfer demonstrated?; and Does it succeed? Two issues of particular relevance to the current chapter can be highlighted here. First, Timms (2011), in the context of EU transport policy transfer, emphasized the potential differences between “top down” perspectives on transfer (as might be exemplified in the type of guidelines reviewed in Section 2) and the “bottom-up” perspectives of specific city transport planners (identified through semi-structured interviews). One conclusion to this research was that city planners receive information from a wide variety of sources, including a variety of professional and personal networks, and

^d <https://brtguide.itdp.org/branch/master/guide/>

^e <https://www.eltis.org/>

Figure 1 10-step transferability process. Source: Macário and Marques (2008).

such information interacted with that provided by “top down” guidelines in complex ways. Second, the paper by Attard and Enoch (2011) presented a “rich” description of the ex-post transfer of a specific policy (road pricing) to one particular city (Valletta, Malta). Although this was the only paper in the special issue that took this approach, it was an approach that would be adopted more frequently in later research (as will be seen in Section 4).

At the same time as the publication of the special issue in *Transport Policy*, research was being undertaken independently to enhance and develop various high level concepts about the policy transfer process, including: *urban policy mobilities and global circuits of knowledge* (McCann, 2011); *transfer-diffusion to mobility-mutation* (Peck, 2011); *institutional isomorphism* (Peck, 2011); *policy tourism* (González, 2011); *worlding practices* (Roy, 2011); and *a range of interests in the policy transfer “business,” such as consultants, advocates, evaluators, gurus, and critics* (Peck and Theodore, 2010). These concepts are all described within a context of “fast” policy transfer consistent with globalized neoliberalism, and make an important contribution to understanding the types of complexity that were identified in the questions posed at the end of Section 2. Many of the transport case studies to be reported in Section 4 make use of these, or similar, concepts, citing the authors mentioned here.

Table 1 Case studies in urban transport policy transfer since 2011.

<i>What is transferred?</i>	<i>From where?</i>	<i>To where?</i>	<i>Authors</i>
Bus Rapid Transit (BRT)	Bogotá	South African cities	Wood (2014a, 2014b, 2014c)

Research on Urban Transport Policy Transfer Since 2011

Since 2011, there has been a large increase in multisectoral academic research on urban policy transfer, frequently using the concepts used by the authors mentioned at the end of Section 3. Some of this research includes transport as one of a number of sectors being considered, awarding transport a more or less important role. Furthermore, there is a large amount of recent research on urban transport policy that makes implicit reference to policy transfer. Reviewing either (or both) of these topics comprehensively (i.e., multisectoral policy transfer and urban transport policy) would go beyond the scope of the present chapter. Therefore, the current section is limited to research since 2011 that concentrates exclusively (or at least mainly) upon the urban transport sector, makes the transfer of transport policy measures a central aspect of the research, and follows on (methodologically) from the research reported in Section 3. Two significant high level conceptual contributions to such research are: Vigar (2017), who explains how transferred knowledge can be incorporated in *communicative transport planning*; and Monios (2017), who distinguishes transport policy transfer from *policy churn*, defined as “changing a policy without establishing a clear link between the reasons for failure of the existing policy and how these will be overcome by the new policy.” In general, though, most of the research on urban transport policy transfer since 2011 has been case-study based: Table 1 gives information about the transport measures and origins/destinations of transfer involved.

A striking aspect of Table 1 is that the range of policies has been relatively limited, with emphasis upon bus rapid transit (BRT), transit-oriented development (TOD), and cycling measures. In general, the research provides many rich insights into the motivations of the particular actors involved in policy transfer. For example, Montero (2017) quotes a study tour participant from

Guadalajara to Bogotá who had heard Enrique Peñalosa (ex-mayor of Bogotá and worldwide “policy entrepreneur” for BRT) give a talk in Guadalajara:

“We thought it would be a good idea to go to Bogotá to see if it was true all that [Peñalosa] told us about the city: how in a city which had 50% of Guadalajara’s per capita income, 40 years of guerrilla, and with rampant drug trafficking ... how could he do that? We didn’t really believe him, we thought he was probably lying ... We needed to see it ourselves to believe it” (p340).

The overall impression from these case studies is that, as might be expected, *good (or best) practice* is far more nuanced than is implied in the guidelines described in Section 2. Furthermore, the case studies provide insights into “policy transfer failures” in two distinct senses: first what might be positively learnt in a particular city about a policy that “failed” somewhere else, for example, a failed plan for an expressway removal in Toronto (Farmer and Perl, 2018), and failed monorail and LRT schemes in Kuala Lumpur, Mumbai, Las Vegas, Moscow, Seattle, Sydney, Jakarta, Putrajaya and Malacca (Connolly, 2019); and second when the transfer process itself was deemed to be a failure, such as the transfer of TOD and BRT to Chengdu (Thomas and Deakin, 2017).

Suggestions for Further Research

This chapter has identified an evolution in thinking about the transfer of urban transport policy measures, taking into account both applied research (as used in the development of good practice guidelines) and academic research (which seeks to understand the complexities involved in the policy transfer process). Two suggestions are given here for further research:

- Rekhviashvili and Sgibnev (2018a) have argued that, in general, more attention should be paid in transport studies to urban transport workers, especially those with precarious contracts of employment, and in Rekhviashvili and Sgibnev (2018b) they discuss the position(s) of Uber drivers and marshrutka^f drivers. Furthermore, as can be seen in Table 1, there is in general a lack of research on the policy transfer of measures concerning informal public transport. It is thus suggested that specific attention should be made on the transfer of regulatory and other measures concerning informal public transport, including measures directly affecting informal transport workers, covering modes such as motorbike taxis (Ehebrecht et al., 2018, Diaz Olvera et al., 2020), auto-rickshaws (Harding et al., 2016) and other forms of paratransit (Cervero and Golub, 2007, Mateo-Babiano, 2016, Phun and Yai, 2016, Jennings and Behrens, 2017).
- Much emphasis has been put on the need for public participation in urban transport planning, both in SUMP guidelines (Rupprecht Consult, 2019, Lindenau and Böhler-Baedeker, 2016) and by transport studies researchers (McAndrews and Marcus, 2015, Sagaris, 2018, Kębłowski et al., 2019). More research needs to be carried out as to how the views of “ordinary citizens” can be incorporated in the public participation aspects of policy transfer processes. Research could pay particular attention to situations where such citizens have expert knowledge on other locations due to having spent long or short periods of time in other countries, or through having international social media connections (McArthur, 2019).

Background and Development Over Time

The concept of accessibility in regards to integrated land-use and transport planning has been a popular research topic for quite a while now (Hansen, 1959). The value of accessibility indicators as planning tools has also been well established, not only as a theoretical means of examining cities, but also as a tool for evaluating transportation policies (Koenig, 1980). While these tools have changed and improved over time, there has been discussion surrounding the practicality and value of different types of accessibility indicators (Geurs and Ritsema van Eck, 2001). Whether or not this wide array of accessibility tools is actually useful or helpful to practitioners is a prominent discussion topic (Silva and Larsson, 2018). The disconnect between the intended purposes of these tools and the actual implementation by practitioners creates an “implementation gap” that needs to be addressed (te Brömmelstroet et al., 2016).

The development of accessibility tools has not been static. Instead, tools have evolved and changed over time in order to take advantage of new technology and meet new demands. For years, tools focused on mathematical accuracy and precision as new technology allowed for tools to measure accessibility in ever increasing detail. However, more detail does not necessarily mean more useful. Finding a balance between these two characteristics is a challenge that still needs to be addressed by academics and practitioners.

The actual value of the abundance of accessibility tools is debatable. On one hand, a push for precision allows for the urban environment to be examined in more detail and with more accuracy, but on the other hand, this increase in complexity and detail is not necessarily useful to practitioners and can create a divide between the intended purposes of the tools and the actual needs of the practitioners. The “implementation gap” that is present in accessibility tools will be discussed further in the second section of this chapter.

Despite the proliferation of accessibility tools—even those that might not be useful to practitioners—new accessibility tools will likely need to be created in order to study the rapidly changing transportation landscape brought on by privatization in transportation markets, the development of new technology, and increased concern for the environmental impacts of transportation. The uncertainty of the future raises many questions about accessibility that need to be researched. Details regarding the future of accessibility tools and accessibility research will be addressed in the fourth and final section of this chapter.

Implementation Gap

The implementation gap in accessibility tools takes shape in three different forms: gaps in the accessibility concept, gaps in the accessibility measures, and gaps in the accessibility tools. More details about these implementation gaps will be discussed in the following sections.

Accessibility Concept

Despite the fact that accessibility as a concept has been known and used by planning practitioners for years, many modern planning policies still lack the requirement to take accessibility into account in urban and transport planning. In a survey of policies in 16 countries, it was found that only three of the countries surveyed had some sort of requirement to take accessibility into account in urban and transport planning (Hull et al., 2012b). The United Kingdom, Norway, and Germany had some sort of requirement to consider accessibility, while in other countries (Sweden, Belgium, Spain, Greece, and Denmark) it was only recommended that planners use an accessibility instrument. Finland, Australia, Poland, Italy, Portugal, Slovenia, and the Netherlands did not have a requirement to perform an accessibility assessment.

This survey highlights a significant issue with accessibility instruments. Despite the abundance of available tools that practitioners could use to measure accessibility in any number of ways for a variety of circumstances, many practitioners are not even required to consider accessibility. The reason for this is not always clear, but the concept of accessibility may not be well understood and the accessibility tools may be seen as complicated black boxes (te Brömmelstroet, 2014).

There is a conceptual mismatch when it comes to accessibility and what it exactly means to take accessibility into account when planning in land-use and transport. Accessibility can take many forms; for whom and for what purpose accessibility should be provided can vary tremendously and a much more nuanced approach is needed to take into account all of the different accessibility possibilities (Silva and Larsson, 2018). Practitioners and municipalities often only consider accessibility as a single goal without contemplating the many different shades and variations that accessibility could be realized. This way of thinking highlights a general misunderstanding of accessibility as a concept (Silva and Larsson, 2018).

Accessibility Measures

As discussed in the previous section, what exactly is included in the concept of accessibility can vary significantly. There are many different variables that could be measured in order to take accessibility into account. For example, time accessibility to jobs or public transport, but also cost accessibility to specific goods or services (Büttner, 2016). That being said, there is often a gap in the accessibility measures that can be used and those that are actually used or should be used. Access to jobs is a measurement that is often used in order to quantify accessibility, which is important, but not the be-all and end-all of accessibility. However, this might be the deciding factor for determining whether or not an infrastructure project receives funding or gets built. While job accessibility is important, using this single measurement in order to make decisions is not a very comprehensive approach and does not take into account the all of the everyday needs of actual people (Silva and Larsson, 2018).

In general, accessibility measures often examine accessibility from one of four main perspectives: infrastructure-based, location-based, person-based, or utility-based (Geurs and van Wee, 2004). Each of these perspectives has a different focus and level of suitability for different needs. However, it is important to note that while these different perspectives are all for measures of accessibility, they are not interchangeable. Geurs (2018) argues that time and time again we can see that conclusions of accessibility are greatly dependent on the type of measure that is used. This highlights the significance of the gap between accessibility measures that are available and those, which are used. While it may be possible to use one measure to assess accessibility, it might not be the most appropriate measure.

In the case of the Netherlands, Geurs (2018) breaks down Dutch national and regional transport planning and identifies five main limitations involving accessibility measures. These five main limitations highlight common instances where accessibility measures might be used by practitioners, but possibly inappropriately.

The first limitation is that planners might understand the significance of measuring accessibility for transportation planning, but other areas that would also benefit from using accessibility measures, such as public health and education, might be ignored. This “sectoral policy approach” misses opportunities to include accessibility measures in areas where they are needed.

The second limitation is that the interactions of land-use and transport are often ignored. While value can be gained by adding accessibility measures to a land-use analysis, land-use and transport are often considered separately.

The third limitation is that policies often focus exclusively on travel time and ignore other transport measures, such as cost or comfort. Individual components are also often ignored. The lack of individual differentiation means that it is not always clear what different levels of accessibility are available to different population groups.

The fourth limitation is that measures to address small-scale urban mobility, such as walking or cycling, and multimodality are often left out of accessibility indicators. While car and public transport are significant, focusing on them alone will not tell the whole story.

The fifth limitation is that the effects on equity are often left out of accessibility indicators. Addressing this limitation, as well as the other four limitations, is necessary if practitioners and academics are going to close the gap between the accessibility measures that get used and the measures that should be used.

Accessibility Tools

One of the most significant implementation gaps for accessibility tools is the gap between the tools that get developed and those that actually get used. Among the plethora of accessibility tools that are constantly being hatched up by academics, a relatively small percentage actually gets used by practitioners. While the cause of this phenomenon is up for debate, there are a number of factors that contribute to the lack of acceptance of these tools.

One possible explanation for the implementation gap of accessibility tools is the disconnect between planning practitioners and the tool developers. The two groups may have different goals and may be unaware of the needs of the other (Silva and Larsson, 2018). The developers of accessibility tools need to walk a thin line between creating measures that accurately represent the intricacies of the urban environment while also being approachable and understandable by all of the stakeholders involved (Hull et al., 2012a). Unfortunately, many accessibility tools often end up too far on one side of that line.

There are a number of barriers to using accessibility instruments that either prevent practitioners from using them, or prevent them from being used effectively. These barriers can be grouped into two main groups, technical/resource barriers and political barriers (te Brömmelstroet et al., 2014). Practitioners are often unsure if their organizations have sufficient familiarity with

accessibility instruments and if their organizations have sufficient resources, such as computational power and funding, in order to effectively use the accessibility instruments (Büttner et al., 2018).

Application of Accessibility in Planning Practice and Policy Making

As discussed in the previous section, there are gaps in the field of accessibility tools. However, it is important to note the accessibility tools that are being applied to planning practice and policy making. Thoroughly examining these can help shine light on which attributes of these tools are assets to the planning process and which attributes are a hindrance to the same process.

Unfortunately, using accessibility tools in planning practice does not always guarantee success and can produce mixed results. An example of this is the ABC location policy in the Netherlands. Enacted in 1990, the Dutch ABC location policy categorizes land into three main types (A, B, or C), then recommends where different types of businesses should be located based on accessibility to public transport. In general, A locations are located close to public transport and have very strict parking regulations, B locations are well-connected to public transport, but outside of city centers, and C locations have no parking limitations and typically have no parking restrictions. The idea is to integrate land-use and transport accessibility into a single policy.

Despite the intention to use an accessibility policy to coordinate land-use and transport the Dutch ABC location policy has been criticized for a few shortcomings. While the intended purpose of the plan is to combat traffic congestion by encouraging companies to locate in appropriate locations in relation to public transport, the actual effects on car-use have been negligible (Dieperink and Driessen, 2000). One possible reason for the limited effects is the poor alignment between the accessibility profiles of businesses and what businesses actually wanted (Dieperink and Driessen, 2000). This means that businesses that the government thought should be located in central areas close to transit were often more interested in being located near motorways and having ample parking.

Another possible reason for the limited success of the ABC location policy is that demand for office space in the 1990s was higher than expected (Schwanen et al., 2004). This meant that even if a business with an accessibility profile that required better access to transit really wanted to locate in an area categorized as type A, the business might not be able to locate there because of office space demands.

Germany has its own planning guidelines that are used to bring accessibility into the planning process. RIN (Richtlinien für integrierte Netzgestaltung) is a guideline that has been in use since 2008, and which specifies how far away people should be from different types of urban centers. These guidelines are noteworthy because they formally integrate public transport accessibility into the spatial planning process.

In Switzerland, the Agglomeration Policy is a national framework for integrating land-use and transport planning in urban regions. One of the key features of the policy is that it coordinates transport planning across multiple jurisdictions as well as across national borders. This is significant because the policy addresses the fact that people do not confine their lives to a single jurisdiction.

In addition to policy measures, easily-used accessibility tools are also available online. The WebCAT tool from Transport for London is an example of this. The interactive web tool visualizes public transport accessibility in London, not only for a base year, but also for several scenarios in the future. While this tool provides less in-depth analysis and detail than other accessibility tools, its primary asset is that it is approachable and user-friendly. This tool can easily be used by practitioners with different skill levels, as well as the general public.

The accessibility tools and policies described above are examples of how accessibility has been integrated into the planning process. Attributes of successful accessibility policies include formal integration of public transport accessibility into spatial planning process, as seen in Germany, cross-jurisdiction and cross-border accessibility, as seen in Switzerland, and approachability/ease-of-use, as seen with WebCAT in London. The shortcomings of the ABC location policy in the Netherlands also highlighted the importance of properly aligning the needs and desires of the different parties and stakeholders involved (Wulffhorst et al., 2017).

Critical Reflection for New Horizons

While the future of accessibility tools is not entirely clear, there are some noteworthy trends and concepts that are worth examining. New planning priorities and ideas may alter the form that future accessibility tools will take.

Climate change and its detrimental effects have moved to the forefront of public discourse in recent years. While this has taken shape in the form of calls to action—and criticism for inaction—there could and should be some overflow into the field of accessibility tools. Municipalities and governments may start to consider new accessibility measures, such as CO₂ emissions, that have previously been left out of accessibility research. Examples of such metrics can already be seen in some recent research (Kinigadner et al., 2019). Kinigadner et al. (2019) look at the effect firm location has on commuting-related CO₂ emissions and demonstrates a method for assessing this. The analysis revealed significant variation in commuting-related CO₂ emissions between firms located in central areas and firms located in peripheral areas. It is possible that newer emission-based measures—such as the one used in this analysis—will become more prevalent in planning practice as municipalities and governments focus more on meeting environmental goals.

Accessibility tools have changed and adapted over the years, but the transport landscape has been relatively stable. However, new technology and transport services have altered the urban-mobility environment and will likely continue changing it in the near future. Ride-sharing, ride-hailing, and car-sharing services have brought private business interests into the transport sector in a way

that was previously unseen. New technologies, such as electric scooters and free-floating bike-sharing systems, have added new mobility choices that were previously unavailable. Future technology, such as autonomous vehicles, will likely further disrupt the transport ecosystem and introduce new challenges. Accessibility research will most likely need to adapt in order to create new tools that can adequately assess the effects of new services and technology on accessibility.

Future accessibility tools might move toward being web-based and take advantage of open-source data. Examples of these types of tools already exist, but may increase in number in the near future. GOAT (Geo Open Accessibility Tool)^a is an example of a web-based accessibility tool that can be used to visualize local accessibility as well as build scenarios on a neighborhood scale while focusing on active modes. The tool is easily approachable, but provides the opportunity to increase the complexity of an analysis to fit the user's specific needs. Tools like GOAT bridge the gap between academics and practitioners by being user-friendly, but also flexible and detailed.

Accessibility planning faces many challenges in the future. Not only will new tools and better coordination with practitioners be needed in order to address the implementation gap, but new tools will also likely be needed in order to evaluate the changing urban mobility environment. With this in mind, an open platform was developed under www.accessibilityplanning.eu. The Meta Accessibility platform is collecting and sorting accessibility tools worldwide in respect to its purpose, functionality and target group. By this, suitable tools can be aligned to specific issues of different user groups (ranging from decision-makers, planning practitioners, and academics to citizens). Taking into account their respective needs the implementation gap of accessibility tools can eventually be overcome.

Introduction

"[Ever] since the French mathematician and philosopher Blaise Pascal began operating what is thought to be the world's first public transport service in 1662, public transport has invariably meant some type of vehicle (or groups of vehicles) shuttling back and forth, terminal to terminal. While there have been variations, e.g., services with formal stops and schedules versus stop anywhere and no schedules, the basic public transport offer has not changed much."

Agarwal et al., (2019, pp. 77)

Unfortunately, while the need for mass transport systems able to move lots of people in as efficient a way as possible continues to become ever more vital to our society, the ability of the traditional methods of achieving that (particularly buses) is becoming less and less effective at doing so. Thus, in Great Britain for instance, the modal share of the bus (as measured as a percentage of billion passenger kilometers) fell from 42% of all trips in 1952, to only 5% in 2017—that is, from 92 to 38 billion passenger kilometers. By contrast car use increased from 58 billion passenger kilometers or 27% of all trips to 670 billion passenger kilometers (83%) over the same period (Department for Transport, 2018). In understanding the reasons for this, perhaps the classic explanation of what has happened is the so-called vicious cycle of decline (Mohring, 1972). Under this model, as society got richer then more people bought cars; and this increased traffic congestion which slowed down buses and led to less people taking the bus; and made the bus still less attractive because either services were cut or fares were raised to cover the increased costs of operating the buses; which meant more people bought cars and increased traffic congestion further; and so less people used buses etc. Not only that, but as car ownership increased, then new housing, retail and employment sites began to be located in areas not well served by public transport which in turn reinforced the steady decline in public transport use still further (Rodrigue, 2017). More recent analysis reported that bus use is suffering due to the availability of viable alternatives to the bus, changing public attitudes, and a series of wider social and economic trends (Bray and Bellamy, 2019).

One long-proposed solution for addressing these problems facing conventional public transport services, has been to introduce a form of public transport that is better suited to operating in these conditions of lower demand, that is, demand responsive transport (DRT). As a concept, DRT systems are appealing to operators in areas and/or at times of low demand, because they theoretically provide public transport users with a service that is higher quality than that offered by a bus, but for a fare that is cheaper than a taxi, and at a cost that is lower than for a conventional big bus. Yet despite the potential scope and appropriateness of DRT for modern transport needs, in practice they remain a niche concern. For instance, a survey of British local authorities revealed there to be a relatively small number of DRT schemes in operation (369 from a response rate of 47% of councils, crudely suggesting a total of around 800 DRT services across the country) compared with roughly 22,000 bus services—that is, about 4% of services (Davison et al., 2014; Stagecoach, 2015). That said, a 2010 survey of 194 transit agencies across the United States and Canada (a response rate of 45%) found that 39% operated some form of DRT for some services (Potts et al., 2010). Moreover, this also showed that DRT schemes were being introduced by a growing number of agencies each decade: thus eight introduced DRT schemes in the 1980s, 18 in the 1990s, 35 in the 1990s and 40 in the decade up to 2010.

Such a status has previously been ascribed to three main barriers: technological, institutional and economic (Cervero, 1997; Enoch et al., 2004; Mulley et al., 2012). In particular, technological challenges tended to relate to optimizing the booking,

scheduling, and routing functions, while institutional barriers included navigating the diverse range of licensing regimes for operators, drivers, vehicles and routes or service areas, which in turn had major implications on insurance, subsidy, tax, VAT, safety and several other operational questions. Meanwhile economic issues focused on the business model underpinning DRT. In sum, small vehicles generally are unable to generate sufficient revenue from the relatively low numbers of passengers often paying relatively low fares to cover the high costs of provision (particularly the driver costs).

The aim of this chapter therefore, is to look at exactly what DRT is, at its evolution over time, and at how it might develop in the future.

Defining and Characterizing DRT Systems

The scope of what are DRT systems and what are not is actually rather blurred, but for the purpose of completeness in this chapter the term will refer to “an intermediate form of public transport, somewhere between a regular service route that uses small low floor buses and variably routed highly personalized transport services offered by taxis” (Brake et al., 2004, p. 324). Similarly, Mageean and Nelson (2003) defined DRT as providing “on-demand [transport] for passengers using fleets of vehicles scheduled to pick up and drop off people in accordance with their needs” (p. 255). They add that it is seen by some as a tool that could fill the gap between a fixed route bus and a taxi in order to meet the needs of certain members of the population. Other related terms include paratransit (of which DRT could be considered as a subset) and flexible transport systems, which is a broadly similar concept. Fundamentally, DRT services may not have fixed routes or timetables but are available to unrelated members of the general public and are usually operated by vehicles that are smaller than a conventional bus.

Characteristics of DRT Systems

There are a wide range of types of DRT. Critical service design features are focused on how the service is delivered, organized, and financed.

Delivery Attributes

The key delivery attributes include how the service is routed, timetabled, accessed by the user, and on the vehicle size chosen. Spatially, DRT services can either follow fixed routes; be semi-flexibly routed and deviate from a fixed route on request (either via the booking system or when already on the vehicle); else be fully flexibly routed and operate within a defined zone. Related to this, DRT services can operate between a single trip origin and a single destination; between a single origin/destination and multiple destinations/origins; or between multiple origins and destinations.

Temporally, DRT can either operate to a fixed schedule (through a number of fixed timing points); operate on-demand, that is, when requested to do so by passengers; else be unscheduled, whereby operators provide services in areas and/or at times when they can expect to be busy—that is, they respond to “historical” patterns of demand.

These alternatives are illustrated in Fig. 1.

Accessing DRT services can be done in various ways. At its simplest, passengers turn up to a terminus or stop and physically request to be allowed to board at the time of departure. Alternatively, passengers can telephone or book through the Internet or via an app.

Lastly, vehicle sizes used for DRT typically range from options including 4–5 seat shared taxi-type services, to 7–8 seat taxis, to 15–20 seat minibuses, to 25–40 seat midi-buses. Decisions as to which sized vehicle to employ are clearly dependent on expected peak loadings, but also on a range of institutional factors around licensing and tax regimes for example (see later for more on this).

Planning the more complex service patterns in an effective and efficient way, particularly for systems with larger numbers of vehicles, has only really become viable with the development of advanced computer software packages (such as provided by Trapeze) since the mid-1990s to process booking requests and make appropriate vehicle and driver scheduling allocations. They can also require passengers to book (sometimes several hours) in advance, and/or require travelers to be flexible in their departure and arrival times. Typically there is a trade-off between service quality for the passenger, and the degree of operational efficiency that is possible. One other routing choice is between whether a service is made door-to-door or merely checkpoint-to-checkpoint, with the former option perhaps being better for the passenger being picked up, but worse in terms of slower journey times for the passengers already on the vehicle and the overall operational performance.

In all these planning and operational regards, technology has been rapidly advancing. Most recently, “Mobility-as-a-Service” (MaaS) solutions allow transport providers to bundle a range of service attributes together into packages, which are then offered to users who can then select the option that best meets their needs via digital transport service platforms that enable users to access, pay for, and get real-time information on, a range of public and private transport options including DRT services (Enoch, 2018). MaaS platforms thus create efficient and dynamic marketplaces for transport due to transparent information flows and minimal transaction costs, and hence could revolutionize how transport generally and DRT specifically is provided and consumed (see later).

Organizational Aspects

The organizational aspects include questions around why and how DRT systems are introduced and operated, which in turn can impact on the types of operators and regulatory frameworks involved. There have been two main motivations for introducing DRT systems—either for commercial reasons or to meet public policy goals. Thus, the majority of jitney operations in cities across the United States from the early 1900s, and a whole range of similar systems that still operate throughout South America, Africa, Asia and Eastern Europe (e.g., Dolmus in Turkey and Mashrukta in Kenya) are operated for profit (*Cervero, 1997*). Typically in these cases, the need for transport is not being met by private vehicles nor by conventional public transport, and hence the DRT operators step in to serve those people. By contrast the public policy driven schemes have generally been targeted at enabling citizens living in areas where demand is insufficient to justify operating conventional public transport services to access facilities (e.g., Regiotaxi in the Netherlands, InterConnect and Cango in the UK) (*Enoch et al., 2004*).

In identifying current and future markets for DRT, *Davison et al. (2012)* devised the following framework in terms of market and product position and potential (**Table 1**).

From this UK 2012 analysis, it can be seen that DRT is currently strongly associated with rural areas and mobility impaired and older people, but that this was predicted to change to a more suburban and working age-type landscape. Interestingly, evidence as to where the most recent DRT service models are now being applied is seemingly following this path, but in addition is focused on large urban population centers.

In terms of ownership, the commercially operated schemes are generally operated by private operators—often owner-drivers or cooperatives, though not always. Meanwhile the public policy driven schemes are run by a much broader range of publicly, privately and socially-owned providers from the very small to multinational organizations.

Finally there are a whole range of institutional complications that can interfere with the development of DRT and indeed other forms of new mobility systems that relate to the diverse range of licensing regimes for operators, drivers, vehicles and routes or service areas, which in turn have major implications on insurance, subsidy, tax, VAT, safety and several other operational questions (*Enoch et al., 2004*). Meanwhile DRT operations are also often excluded from a whole range of institutional and financial support due to policies and financing mechanisms that define public transport according to the existing large vehicle/corridor system model. One approach in simplifying this could be to regulate the day-to-day aspects of each transport operator (driver licensing, subsidy allocation, etc.) almost as they are now, but then to classify operators by their level of specialism (e.g., occasional, regular, specialist),

Table 1 Demand responsive transport market and product position and potential

	<i>Existing/strong products Market penetration</i>	<i>New/less certain products Product development</i>
Existing/strong markets	Rural, general public Without access to car and conventional public transport Mobility impaired Non-emergency patient transport Shopping, suburban and rural, general public Educational establishment for students with special educational needs Market development	Urban orbital, general public Airport access for passengers and employees (Market penetration in USA and Europe) Workplaces, outside urban core, employees Hospitals and other destinations, specialist needs Diversification
New/less certain markets	Educational establishments, rural, students Trip attractors, rural areas, tourists Integrated DRT supply for the general public	Suburban, general public (Product development in USA) Entertainment venues in urban centers Sport venues, ticket holders Meeting and conference venues, employees Services and good to rural areas

Source: Davison et al. (2012).

whereby the more specialist the operator, the tighter the regulations but the greater the operational benefits and opportunities (Enoch and Potter, 2016). This would mean that DRT modes for example, would no longer be forced into operating pre-conceived service patterns (constrained, for example, by limitations on number of seats, timetable schedules, route/area restrictions); and should allow for occasional providers to “safely” join the transport market as the opportunity arises.

Financial Elements

Establishing and maintaining the financial sustainability of a DRT system is perhaps the most challenging issue facing scheme promoters. Indeed, lack of financial viability is one of the commonest reasons for DRT schemes failing. This is partly a result of operating in areas of low demand. While for public policy schemes (which are often aimed at reducing levels of social exclusion) this is due to the inability to price the service at a rate that does not get close to reflecting the costs of providing it. In practice, this means that the traditional “big bus” commercial funding model, whereby one large vehicle on a major route packed with passengers for one journey in the morning and one in the evening can essentially cross-subsidize journeys for the rest of the day and across the network is not an option. The two fundamental approaches available to operators to secure a financially sustainable future are to raise revenue or to cut costs. Raising revenues can be done either through increasing monies from fares, through attracting more users and/or by increasing fares; or else by drawing in more budget from other sources. Thus, for the commercially driven “jitney-style” schemes on high-demand corridors that are otherwise poorly served by public transport, operators aim to fill up their vehicles with as many fare-paying riders as possible, often not even setting off until they are full. Next, airport shuttles in the United States charge a fare somewhere between the public transport and airport taxi rates, so reflecting the intermediate quality of the journey experience. By contrast, most public policy motivated scheme promoters are loath to charge more than a standard bus fare (generally with good reason) in spite of the far higher cost of providing those services, and hence their services require significant levels of subsidy. Interestingly, one slight exception is that of St Joseph Transit in Kansas City, Kansas, which charges a \$0.50 supplement for passenger wishing to deviate from the route (Potts et al., 2010). Consequently, marketing services can be crucially important ways of increasing DRT patronage, which Potts et al. (2010) recommend doing through community groups, events, targeted mailings, internet sites and posters/leaflets/brochures. Other mechanisms for covering costs, are to generate ancillary revenue streams, rely on local authority subsidies, or attract new monies from alternative external sources. Thus, for many years Lincolnshire County Council has offered its call centre services to neighboring DRT-operating local authorities and has successfully bid for additional funding from various national and European pots. And the PickMeUp DRT scheme launched in 2018 in Oxford, UK is partly financially supported by employers.

Cutting costs has been done by rationalizing service levels and by making efficiency savings. For instance, Wiltshire County Council, UK consolidated its DRT provision following a strategy review in 2006, while Flintshire Council, UK ended up replacing the demand responsive component of its Deeside Shuttle service in 2015 to reduce passenger subsidy levels. Further efficiency savings have also been sought through different transport providing agencies in Somerset, UK sharing access to their vehicles (e.g., community transport, social services, education, public transport operators and voluntary groups) through a brokerage-based Integrated Passenger Transport Unit approach. Enoch et al. (2007) added that it is also necessary for agencies to secure political support based on a strong strategic vision of how DRT is integral to delivering social inclusion, environmental and economic goals—and so make the services less vulnerable to cuts than otherwise. Finally on cost cutting, the development of autonomous vehicles

Figure 2 The evolution of DRT systems.

could have significant impacts in the medium term, with a number of tests currently being carried out with driverless buses around the world.

The Development of DRT

Pulling these strands together, looking back at the evolution of DRT over the past century in many countries around the world, we can see two distinct DRT operational phases in place, while we now seem about to enter a third (see Fig. 2).

Phase 1: 1920–1969

Under the first phase, “informal” DRT services such as jitneys have operated across the world since the early 20th century. These were/are relatively simple and low-technology minibus or shared taxi-based systems that operate for a profit and typically serve low-price market niches on busy corridors that are underserved by conventional public transport services. Passengers generally turn up at a terminus or hail from the roadside but can book ahead by phone in some cases. Services usually operate on demand as opposed to by a fixed timetable, along corridors with drivers sometimes deviating on request, and fares are broadly comparable to bus fares—sometimes slightly less, or slightly more, depending on whether they are perceived as being of lower or higher quality. Examples of such schemes still operate in countries as diverse as Tunisia, Russia, Mauritius, Kenya, the Philippines, Cuba, Northern Ireland, and the United States.

Phase 2: 1970–2019

The second “dial-a-ride” operational model began to emerge in the 1970s and 1980s, when public policy driven service types began to be trialed, for instance in cities such as Milton Keynes, UK and Merrill, Wisconsin (Flusberg, 1976). This “medium technology” model operated on the basis of passengers booking a seat on a minibus for a trip to be made within a specific time window usually at least an hour (often 24 h or more) in advance, so that the operator could then manually allocate the drivers and vehicles to the most efficient service pattern within a particular operational area (Kirby et al., 1974; Nutley, 1990). Unfortunately however, these operations were nearly always heavily subsidized and often failed for all but the most specialist trips due to the labor-intensiveness of the system, high labor costs and inefficiencies such as many service vehicles travelling without or with few passengers. Another reason for low performance was that the systems were simply not attractive to consumers (Khattack and Yim, 2004).

Subsequently, advances in software, computers, digital maps, expert systems, remote communications, in-vehicle computers and GPS from the late 1990s led to DRT steadily becoming more technologically viable in the late 1990s (Duffell, 2003). In Britain and

some countries elsewhere, these developments were stimulated for a period by the availability of government funding aimed at overcoming social exclusion and resulted in a sudden explosion in the take up of DRT, primarily by local authorities, but also by community transport (CT) operations, commercial public transport operators and even employers (Enoch et al., 2004). In recent years, however, with the removal of the government subsidy, many of the local authorities administering these schemes have faced difficult choices over how to proceed.

Phase 3: 2020 Onwards

Going forward, there are already indications that we are entering a third operational phase known as “micro-transit,” this time based on so-called transportation network companies (TNCs). In this context, sizeable multi-national companies such as Uber and Lyft are now trialing a range of innovative mobility services, including some like Uber POOL and Lyft Line, as well as smaller start-ups such as Go-Opti—which use on-line brokerage portals known as Digital Service Platforms to match taxi and minibus drivers with (unrelated) people wanting to make similar journeys, to encourage them to make their trips together for a lower fare than if they made them separately. This high-technology approach is commercially driven and appears to have the potential to be profitable at some point in the future in some areas at least. This is by virtue of “big data” and “machine learning” methods being used to vary prices for users and payments to drivers according to the relevant levels of demand and supply in real-time and across the network. Unfortunately though, they have not yet made money, and indeed several other micro-transit schemes such as Charriot, Slide, Kutsoplus and Bridj have subsequently stopped operating.

TNC operators are also in the process of working with local authorities in the United States and Canada to provide such DRT services as an alternative to buses—whereby the councils subsidize trips made by the Uber or Lyft to help them meet public policy goals—though in practice one imagines only a few of these are likely to be shared between unrelated passengers.

Future Implications

More broadly, Enoch (2015) and Enoch and Potter (2016) suggest that such a shift toward these microtransit DRT-type modes is likely to accelerate due to a range of factors that are pushing away from the conventional modes of car, bus, taxi and indeed traditional DRT. These include:

- More elderly people who will no longer be able to drive but who need access to places buses serve poorly; more younger people excluded from car ownership by high insurance costs and competing demands on their incomes;
- A number of deep-rooted economic and social factors that are leading to travel demand becoming increasingly dispersed in time, space and across functions.
- A growing culture of “collaborative consumption”;
- Increasing pressures on the global economy and the impact of the austerity agenda in many countries on revenue budgets. Expensive public transport infrastructure projects will be difficult to fund and bus subsidies hard to justify compared to commercial paratransit;
- The political desires to deregulate policy sectors and promote “choice” as a means of improving service quality;
- The increasingly blurred boundaries within the intermediate transport mode supplier sector and the increasing range of “new mobility solutions”;
- The increasing desire to better integrate transport options to create a more user-friendly transport system, through spatial, temporal, ticketing, information and seat brokerage MaaS mechanisms;
- The widespread adoption of big data technologies such as the Internet, smartphone, and GPS tracking technology; and
- The likely adoption of autonomous vehicle and connected autonomous vehicle technologies.

Overall, as with public transport generally, traditionally DRT services were introduced and operated based on (poor quality) ad hoc historic, averaged and aggregated data; operators were legally required to provide the services they are registered to whether used or not; and DRT users had very little direct influence on the type/level of service they received. In future, and with MaaS, transport users and providers will instantaneously communicate their needs via Digital Service Platforms (DSPs)—that is, two-sided markets or brokers—which, for a suitable charge, then make the most appropriate journey match (Djavadian and Chow, 2017). This means that:

- Users can now tell (multiple) operators of (multiple types of) transport service exactly the attributes they want from a transport service: time of arrival, origin and destination points, degree of flexibility, type/level of comfort required, and price they are prepared to pay;
- Providers, which now number many more and now offer many more different types of service than previously, can choose to respond, or not;
- Users, providers and regulators can readily monitor service availability and hence adjust their travel behavior, market strategy, or policy decisions accordingly.

In practice, providing that the regulatory agencies can overcome the various institutional challenges referred to earlier, such MaaS-type platforms could potentially mean that the supply of and demand for DRT and other transport services will be actively managed in near-real-time and in parallel—something which has not been possible before (Hensher, 2017). This should result in DRT services becoming more tailored to needs of users, while the supplier base will become more diverse and flexible. From this, it becomes possible to foresee instances where a commercial case for DRT begin to emerge, as the final barrier preventing the widespread adoption of DRT, that is, the economic viability, is overcome—particularly should driverless technology be adopted on a large scale.

Introduction

The climate change emergency is well-documented, even gaining widespread public attention as the ‘climate crisis’ is made more visible by activists such as Greta Thunberg (2019). We are aware that humanity faces an existential crisis in relation to climate change. Yet strategies to meaningfully reduce carbon dioxide (CO₂) emissions and limit environmental damage lack cohesion and political willpower. There are large problems in implementing appropriate projects, which significantly contribute to reducing CO₂ emissions, and this is particularly the case in the transport sector.

This chapter argues that current discourses and policy responses surrounding sustainable transport lack the boldness and urgency required to confront the climate emergency. Over reliance on technological solutions to decarbonize the transport network, amid premises of economic growth, fail to address the causal problems of increasing consumption and mobility and hence transport CO₂ emissions. Reducing transport-related CO₂ emissions demands radical cultural and behavioral changes at individual and societal levels—and this requires structural changes including political and cultural dimensions. The approaches used in transport planning can also be widened, to include a greater use of social science perspectives alongside the current strengths in quantitative, predictive analysis.

Current Emissions from Transport

During the last century, anthropogenic (human) activity has led to significant climate change, including surface temperature rises, over a relatively short time period (Intergovernmental Panel on Climate Change, 2014). Alongside there has been much intransigence and difficulty in changing policy approaches, project investments and ultimately in reducing CO₂ emissions.

Aggregate CO₂ emissions across all sectors, including industrial, residential and transport, are given in Fig. 1, using data from the Emission Database for Global Atmospheric Research (EDGAR). There are huge differences in CO₂ emissions by country: China is the largest aggregate emitter at over 10.5 GTCO₂ (7.6 tons CO₂ per capita), the US at 5.3 GTCO₂ (a higher 16.5 tons CO₂ per capita) – these two countries account for nearly 45% of global CO₂ emissions. There are other large emitters in India, Russia, Japan, Germany, Canada, Brazil, Mexico and the UK. Very large growth in emissions from 1990 to 2014 is seen in China, India and Brazil, with China increasing emissions by over 300% and India by 250% from 1990 to 2014 (Hickman et al., 2017). There are complexities in interpreting the data. For example, focusing on aggregate national emissions overlooks large individual and spatial differential within countries. In addition, allocating industrial emissions to producing countries rather than those consuming the products, and indeed ignoring historical emissions, means that the assumed accountability of industrialized countries is reduced.

Transport is a significant contributor to CO₂ emissions and as a sector is responsible for around 20% of all carbon emissions globally. Oil is the dominant fuel source for transport, with road transport accounting for over 80% of energy use—hence the use of fossil fuels makes transport a major contributor to climate change (Chapman, 2007).

Indeed, transport is the only sector increasing its CO₂ emissions over the past decades as any fuel efficiency gains are offset by increases in mobility (Hickman and Banister, 2014). Within OECD countries, transport accounts for 29% of all emissions. Countries differ quite markedly in percentage contribution of transport relative to all CO₂ emissions—the US at 33%, UK at 29%, India at 12% and China at 9% (World Bank, 2015). This reflects many factors, including the levels of mobility, the shape of the built environment, emissions from other sectors and power supplies.

Figure 1 Global aggregate CO₂ emissions. Source: From Hickman et al. (2017), using EDGAR 2014 data.

At the aggregate level, the planet has already warmed 1.5°C above pre-industrial levels, causing “multiple observed changes in the climate system”. Even another half-degree increase will result in more extreme temperatures, floods, storms, precipitation, drought, which will in turn jeopardize water, food, and health security, disproportionately affecting the poor and vulnerable (Intergovernmental Panel on Climate and Change (IPCC), 2019). For example, the IPCC’s 2019 Special Report on Global Warming of 1.5°C warns:

“Such change would require the upscaling and acceleration of the implementation of far-reaching, multilevel, and cross-sectoral climate mitigation and addressing barriers. Such systematic change would need to be linked to complementary adaptation actions, including transformational adaptation . . . Current national pledges on mitigation and adaptation are not enough to stay below the Paris Agreement temperature limits and achieve its adaptation goals.”

It is still unclear how the transport sector can effectively respond to the climate change problems. There are few, if any, countries and cities with forward-looking strategies that demonstrate appropriate, quantified responses. The two most emitting modes (air and personal vehicles) are also the fastest-growing in use, and efficiency improvements in car technology are undermined by the increasing number and size of vehicles (Chapman, 2007). Indeed, significant streetspace reallocation, from the car to public transport, walking and cycling; and air travel demand management; are rarely discussed even in the ‘progressive’ transport planning cities. Consider, for example, London, a city with a well-known sustainable transport strategy (Transport for London, 2018), but which says little on progressive traffic space reallocation or longer distance inter-urban or international travel, with five major global airports in the city-region (Hickman et al., 2010).

Despite international bodies’ dire predictions and the escalation of climate activism in recent years, transport CO₂ emissions continue to move upwards. Achieving a global decrease of over two-thirds seems difficult to comprehend, and virtually impossible to achieve, given that the US, one of the planet’s most intense polluters, confirmed its withdrawal from the Paris Agreement by 2020. Even where cities and national governments introduce projects and initiatives to reduce CO₂ emissions, they are often offset by parallel increases in highway capacity. There is little analysis concerning how overall CO₂ emissions can be significantly reduced. Private industry, without financial incentives or legislative pressure, largely continues ‘business as usual’ operations, and travel behaviors remain unaffected.

Sustainable Transport Amid a Growth Agenda

The need to reduce CO₂ emissions—to consume, build and travel less—conflicts with economic growth agendas that promote the opposite of this. “Sustainable development” is typically defined in an abstract manner, without measurable indicators, providing room for interpretation and claims of sustainable development free of scrutiny (Castro, 2004; Swyngedouw, 2007).

The most commonly deployed definition, from the Brundtland Commission (World Commission on Environment and Development, 1987), is:

“Development that meets the needs of the present without compromising the ability of future generations to meet their own needs.”

However, as [Turcu \(2018\)](#) counters,

"It does not give an indication of what sustainability is precisely and what one may contemplate to measure. For example, what needs, what type of ability, which generations, and over what period of time?"

These issues remain unresolved in relation to sustainable mobility. The main application of sustainability in transport is through the conventional 'three pillars' concept that draws on environmental, social and economic dimensions. This assumes that equal weight is given to all pillars in the process and that a solution can be found that contributes well against each of the economic, social and environmental objectives. Yet, in practice, this rarely happens and the economic pillar is given much greater weight in the decision-making process ([Hickman, 2019](#)). All of this occurs within a growth paradigm, where transport investment is used to support urban development and economic growth. In the end, transport investment is sustaining growth rather than helping to achieve sustainable transport ([Hickman, 2017](#)).

The [OECD \(2000\)](#) attempt to give some definition to the process, defining environmentally sustainable transport as:

"Transport [that] does not endanger public health or ecosystems and meets needs for access consistent with (a) use of renewable resources below their rates of regenerations, and (b) use of non-renewable resources below the rates of development of renewable substitutes."

This aims to give greater weight and precision to the environmentally sustainable transport concept, using indicators that can be quantified. But, many countries and cities are working with only a fuzzy concept of sustainable mobility and this is interpreted in varied ways by different actors, becoming almost meaningless as a working concept.

Visioning and Backcasting

A visioning and backcasting approach can help to give a greater certainty to policy development and the direction of interventions. The concept of 'backcasting' was developed in the 1970s and 1980s to examine how different environmentally sustainable futures might be attained ([Lovins, 1977](#); [Robinson, 1982, 1990](#)). It was applied in the transport sector by authors such as the [OECD \(2000\)](#) to help understand what this might mean in terms of an environmentally sustainable transport system. The approach has since been developed and used in a range of transport studies, including in different contexts ([Åkerman and Höjer, 2006](#); [Geurs and Van Wee, 2000](#); [Hickman and Banister, 2007, 2014](#); [Hickman et al., 2010](#); [Soria-Lara and Banister, 2017](#), amongst others).

[Robinson \(2003\)](#) developed and pioneered the backcasting approach:

"Not to reveal what the future will likely be, but to indicate the relative feasibility and implications of different policy goals"

This is viewed in relation to varied and specific societal problems. Because of this, the various modeling approaches:

"Need to be able to show the implications of different user choices but not choose the most likely or optimal (e.g. least cost) solution. The resultant models act in part as accounting frameworks, which show the consequences of different behavioral choices, rather than predicting most likely outcomes" (ibid).

Backcasting is hence a method to analyze future options concerning long-term complex issues, involving many aspects of society as well as technological innovations and change ([Dreborg, 1996](#)). Rather than develop scenarios extending from the present-day, it considers pathways back from a future state ([Hickman and Banister, 2014](#)). The backcasting process is given in [Fig. 2](#).

Figure 2 Visioning and backcasting. Source: [Hickman \(2020\)](#)

There are four key stages, all of which can be carried out in a participatory manner with local actors, stakeholders and even the public.

- Stage 1: Understanding of local problems and opportunities, BAU projections
- Stage 2: Development of vision for sustainable mobility, this may include key targets and an Avoid-Shift-Improve strategy (discussed below)
- Stage 3: 'Backcast' trajectory to give an implementation program for projects and initiatives
- Stage 4: Evaluation of progress and refinement of the vision, strategy and program

Although backcasting has been put forward as a useful process for implementing changes towards sustainable urban mobility (Hickman and Banister, 2014; Quist et al., 2011), its application still seems largely confined to academic research. There is little use in transport planning practice, for example in strategy development or appraising projects, which still seem entrenched in forecasting and 'predict and provide' analytical approaches.

The problem remains that there is too much motorized travel in many contexts—and forecasting-based approaches will struggle to break long-established trends. There needs to be a much greater effort to significantly increase the mode share of public transport, walking and cycling, across multiple cities and for travel between and beyond cities. There are progressive targets for achieving 80% or more of trips by noncar modes in selective cities, such as London (Transport for London, 2018)—but most urban areas do not demonstrate this awareness. Even for London, this will be difficult to achieve, particularly for travel in the outer suburbs. But, for wider cities, there are probably unsurmountable problems.

This is an exciting agenda for transport planning and transport planners—to provide transport systems that enable sustainable travel behaviors. However, it will be hugely difficult to retrofit existing dispersed cities with high quality public transport networks and sufficient densities to make public transport work at sufficient usage levels. Much of the public debate does not support the removal of traffic capacity and providing improved walking and cycling environments. This is why the visioning and backcasting approach can be very important: helping to discuss and agree future implementation pathways which may be very different to the business as usual trajectory in many contexts. For example, some of the North American dispersed cities have very poor public transport networks, and public transport, walking and cycling are used in less than 10% of trips. Hence there are different development pathways available to cities—but all must try to reduce private car usage due to the very large adverse impacts on society.

Avoid-Shift-Improve

The Avoid-Shift-Improve (ASI) framework (Dalkmann and Brannigan, 2007) offers a way forward for implementing sustainable mobility. It can be used to frame the strategy, which is constructed to implement the vision. Originating in Germany in the early 1990s, the ASI framework brought together the sustainable transport policies being developed at the time, and challenged the conventional "predict and provide" approaches, which often led to highway building. The ASI framework was embraced by International Non-Governmental Organisations (NGOs) as a wide-ranging approach for moving towards sustainable transport. It is similar in concept to the sustainable mobility paradigm (Banister, 2008), encouraging a range of interventions within a transport strategy (Fig. 3).

The measures within each theme can include (Hickman and Banister, 2019):

- Avoid: urban planning, affordable housing, development restraint in inaccessible locations, and reduced growth in international air;
- Shift: improved walking and cycling facilities and networks, multimodal public transport; use of urban highway re-prioritization, travel demand management, emissions-based road pricing, car parking supply restraint, Mobility as a Service, and urban logistics management;
- Improve: shared vehicle ownership, low emission vehicles and alternative fuels.

Figure 3 The ASI framework. Source: Based on Deutsche Gesellschaft für Internationale Zusammenarbeit GMBH (GIZ) (2019).

In some contexts there is progress being made with reduced levels of motorization and higher usage of public transport, walking and cycling. This has been described as the ‘peak car’ phenomenon (Goodwin and Van Dender, 2013; Millard-Ball and Schipper, 2010). A number of factors are attributed to this reduction in car use. These include the increasing cost of owning and maintaining a vehicle, including fuel; modifications to the built environment to de-prioritize cars over other modes of transport; urban densification; increased availability and lower (relative) prices of alternative long distance modes (rail, air); and a cultural change that devalues the status of the car. Many of these are impacts of the sustainable transport policies implemented over the last few decades.

Metz (2013) describes:

“A new era of travel . . . in which average per capita growth of daily travel has ceased”

This is attributed to a maturing of economies caused by a combination of access to more consumer choices, saturated markets and lessening demand for travel, combined with difficulties in traveling faster. It is difficult to travel greater distances if we end up spending too much time traveling. In addition, younger demographics are also eschewing becoming licenced drivers and car owner, and moving to urban centers where car ownership may not only be unnecessary but inconvenient. However, any peak car trend is limited to the Western industrialized countries, remains marginal, and is offset by very significant increases in motorization in the Global South countries. Sustainable urban mobility behaviors are yet to be conceived and implemented in many contexts.

Technological Optimism

A problem for many governments is that there is reliance on technological options to reduce transport CO₂ emissions, hoping that mobility levels and patterns can be maintained, but made cleaner (Hickman and Banister, 2014; Schwanen et al., 2011). As Lyons and Davidson (2016) remind us:

“Our fascination with technological advance, coupled with technological optimism, can cloud our ability to make sense of particular technological possibilities in terms of the extent to which they may become transformative and mainstream, and over what timescale”

New technologies are over-hyped, and particularly in transport. Often they are poorly delivered and any gains in emission reduction are offset by increased mobility. Similarly, Goulden et al. (2014) caution against technical solutions to solve the problem of high carbon mobility because of rebound effects, in which improvements in efficiency lead to increased demand and shape how efficiency is utilized. Rebounds (Sorrell, 2007) include improved fuel economy or increased comfort leading to longer distances traveled. The result is that CO₂ reductions are less than expected.

Regime and Structural Change

The Paris Agreement calls for regime changes, but most of the policies and plans used within transport planning are regime-compliant and not regime-changing.

“The reality on the ground in most countries . . . is that aspirations expressed in the Paris Agreement do not match-up with levels of action” (Ford et al., 2018).

“Business as usual” is likely to result in a 3°C increase in global surface temperatures, with uncertain catastrophic proportions. Regime compliancy is also embedded in the approaches and models used for transport and land use planning (Ford et al., 2018). Where drastic systemic change at institutional, societal, and individual levels is required, many governments instead prefer to implement voluntary incentives, or “nudges” that “create an illusion of choice, seeking to achieve collective goals without directly challenging the neoliberal paradigm” (Goulden et al., 2014).

Lyons and Davidson (2016) similarly question if planning and policy initiatives within the current global regime can lead to meaningful change. “A regime encapsulates the way of the world as we know it and within which the various actors engage.”

Transition theory perhaps offers a way forward in seeking to understand the different potential components of the transition to more sustainable behaviors, particularly when viewed through the multilevel perspective (Geels, 2012; Kemp et al., 2012; Schwanen et al., 2011). This includes niche, regime and landscape levels, all of which combine to influence travel behaviors. For example, the electrification of the vehicle fleet, or indeed other policy measures, can be viewed in terms of how the niche activity enters into the existing regime. The regime includes the key actors in the transport sector, such as the motor manufacturers, urban developers, bus and rail industry, government organizations, transport consultants, civil society and academia. All of these influence the transport system, shaping the infrastructure and network that is available. At the higher level are landscape factors, framing and influencing the regime and niche levels. These landscape factors may include climate change, socio-demographics and the political framework. This broader view of how change may occur helps us to understand that the use of infrastructure investment is also dependent on existing actor, network and power structures, the political and cultural context, and can change over time relative to changing knowledge and innovations. This is a more sophisticated understanding of potential change in travel behaviors and the factors that may be at play.

In recent years there has been progress made in drawing wider disciplines into transport research. Transport psychology has helped us to understand how individual attitudes may influence behaviors (Anable, 2005; Steg, 2005) alongside the transport infrastructure and built environment. This is complemented by an understanding of the wider sociology of travel, including social and cultural norms and political structures (Shove, 2014; Urry, 2006). Transport planning, in academic research at least, now draws on varied disciplines to help explain behaviors and the potential for change in terms of reducing transport CO₂ emissions

(Schwanen et al., 2011). This has been a great progression in helping to understand that enabling changes in travel and achieving reductions in transport CO₂ emissions are actually quite complex. This involves much more than building infrastructure, and potentially individual attitudes and societal structures also need to change. Building high quality public transport networks, improved cycling facilities and public space will help change individual attitudes and societal norms, but also the causality may be required and occur in reverse.

The current regime of motorization has arisen over the last century and has become entrenched in both its geographic reach and cultural symbolism (Lyons and Davidson, 2016). The car dominates the built environment and the fossil fuel industry is inordinately powerful in influencing transport policy to remain centered around the car. “Regime-compliant” policy pathways are often put forward to maintain the implicit reliance on motorization continuing uninterrupted. The conclusion is that the regime needs to change (Böhm et al., 2006) beyond the insignificant revisions usually made at the margins.

Conclusions: Improving Progress Toward Sustainable Mobility

The concentration of the global population into cities presents planners with the opportunity to influence travel behavior so that it can be much less carbon intensive. The projected urban growth can be the catalyst to reducing transport CO₂ emissions, as there will be high demand for new infrastructure and feasibly high proportions of the population will live close to public transport systems. But, implementing the ASI framework in multiple cities demands international cooperation, national and city leadership, and radical policy choices to be developed, agreed, and implemented.

Visioning and backcasting approaches offer a way forward for planning and policymaking, through which sustainable mobility futures can be discussed. Outdated “predict and provide” models should be replaced with scenario building and demand management. Forecasting-based approaches have become obsolete as they offer only marginal changes to the historical trajectories. Transport planning hence becomes a normative and participatory exercise and should be much less interested in predictive modeling and causality. Qualitative approaches, informed by the range of social science perspectives, can help strengthen the conventional use of quantitative analysis in transport planning. For example, we can ask what our desirable future cities and travel behaviors are—and seek to deliver these.

The ASI framework can be used to help define and apply a wide-ranging package of transport interventions within the strategy, including avoid, shift and improve measures. A greater radicalism is required in implementing public transport, walking and cycling projects, travel demand management measures and the reallocation of road space. There also needs to be a focus for transport planning beyond the infrastructure and built environment—the individual attitudes and societal structures need to be shaped to help enable sustainable travel behaviors. Without this, the radical and innovative projects cannot be implemented: the politicians and public will not accept them. There remain many current policy taboos (Gössling and Cohen, 2014), but these can be overcome as the level of public understanding of climate change and the potential solutions are discussed.

There is much discussion, in the transport industry and governmental organizations, concerning what we perceive as false promises of technical innovation to revolutionize the sector. The debate also needs to include reduced consumption and a more transparent understanding of sustainability itself. The major characteristic of backcasting is a focus on how desirable futures can be achieved. This can be the central approach to developing low CO₂ transport futures as it offers such a persuasive combination of vision development, definition of implementation pathway and delivery, all within a strengthened participatory and deliberative perspective. The climate crisis is now very evident—transport is the key sector that needs to improve its performance in reducing CO₂ emissions.

Introduction

Taxicabs and microtransit are types of for-hire vehicle services that have received substantial attention by policymakers, planners and private investors since smart phones became ubiquitous, allowing for applications that connect riders and drivers with more ease and convenience than dispatch models traditionally used. The traditional taxicab market has been transformed by the development of ridehailing, creating expanded service and ridership for private trips. Microtransit maintains the on-demand aspects of taxicabs and ridehailing, but offers services with shared vehicles, from SUVs to small buses. There has been considerable interest by researchers and policymakers as to where expanded taxi and microtransit services fit within urban transportation systems, and whether they act as complements or substitutes for conventional transit.

Taxi and Microtransit Regulation

In most places, taxicabs are regulated by cities to manage fares, limit entry to market, ensure geographic reach, promote public safety and maintain other service characteristics. Microtransit is also locally regulated though with somewhat different requirements, depending on the city, state, or province. The for-hire vehicle industry has been subject to license requirements since its beginnings. The history of regulation includes cycles of strengthening and weakening regulations—the current ridehailing era is one of deregulation. Taxicabs are area of local transportation policy where there is substantial variation in regulatory approach across cities throughout the world. For both taxi services and microtransit, cities and transit agencies have explored some partnerships to improve service, though to date these have had mixed results for ridership costs.

History and Legality

Taxi services have been regulated since their invention. The cycle of regulation and deregulation is central to the history of these services. London and Paris were the first cities to regulate the taxi market, starting in the early 1600s. The cities required licenses for horse drawn hackneys and limited the total number of licenses issued. Such limits on the number of allowed vehicles have been a main feature of local regulations. While the original intent to ensure that operators met minimum quality and safety standards, limits to entry are problematic and lead to rent seeking and monopolistic behaviors.

There are many reasons why taxi services have been historically regulated, some of which can be assuaged through new technologies. First, unlimited entry leads to too many operators competing for too few fares, which depresses wages and is problematic for vehicle maintenance. Second, taxi services are credence goods, in that the riders do not know the correct value of the service. Regulating fares and service areas helps mitigate these concerns, and the smart phone apps of ridehailing and microtransit services can offer transparency in this regard. However, ridehailing firm Uber has also used their app to create “ghost cars” that give the impression of more service than exists, and drivers and passengers are shown different fares. This latter instance is a form of arbitrage, where Uber collects and keeps the difference between what drivers are willing to accept for a ride and what passengers are willing to pay. Third, for many reasons the operators of taxi services, and presumably microtransit, favor exclusionary regulation that keep profits flowing.

For hire services are regulated at local level in most cases. Cities, counties, and other regional governments design and enforce the regulatory environment. In the United States, states either allow cities to regulate taxicabs as part of their police powers, or in some instances states require that cities regulate the industry. There have been numerous court challenges questioning the legality of local taxi regulations but the abilities of cities to regulate the market has nearly always been upheld. The current era of new smart phone applications—discussed in more detail in a later section—represent a new line of legal inquiry that may yet prove the undoing of the historical regulatory structure, but early court cases from technology companies against the taxi industry and regulators present mixed success for the challenges.

Market Structure

Local control over taxi markets means that taxi markets are structured differently across cities. Microtransit is too new a service to have a clear sense of the regulatory structure. Hiring taxi services have historically been categorized as either street hail or dispatch models. In a few cities, such as New York, street hails are the only way to hire a Yellow Cab. In many other cities, street hails are illegal and taxicabs must be dispatched (or booked), yet other cities feature taxi stands, and often airports have their own systems for hiring cabs. There are also regulations about sharing taxis and where drivers are allowed to pick up passengers.

Street Hail

Street hails occur where taxi drivers cruise around in search of fares. Potential passengers flag—or hail—a car from the curb. Most cities prohibit street hails as a means of hiring a car as street hails increase the potential for discrimination based on geography or appearance. Street hails also require price regulation to eliminate fare negotiation at the point of hire. The largest justification for not allowing street hails is that taxi drivers will only cruise in the neighborhoods where they will be able to find an adequate number of fares. This means that taxis searching for street hails tend to cruise in a few parts of any city, usually in the Central Business District (CBD) or at the airports, meaning that much of the area that potentially can be served is not. More critically from a policy standpoint is that the concentration of taxi activity in a wealthy commercial area precludes taxi services in areas outside of the downtown.

Street hails are also potentially a problem with regard to discrimination based on what a passenger looks like. In New York City, the yellow cabs, which are limited to street hails by law, are required to take any fare for which they stop. Of course, this leaves open a great deal of interpretation. Stories of racial and ethnic discrimination are common where taxicabs simply would not stop for a hail. While the fares not picked up are hard to measure beyond anecdotes, more common are fares refused once a taxicab stops. Research on discrimination from ridehailing companies suggest that booking a ride through a smart phone app reduces discrimination of pick-ups ([Brown, 2019](#)).

Pre-booked

In contrast to hailing taxicabs many cities require pre-booking or dispatch models for service. Dispatch services work where the rider calls a central number, or in some cases the taxi driver directly, and a taxi is sent to pick them up. Pre-booked services also include cars that shuttle passengers to airports, limousines, and other commonly used services.

There are multiple justifications for pre-booked services. Cities that wish to prevent discrimination based on location or appearance seek to limit cab driver discretion in choosing fares. Absent dispatched services few taxis cabs would be found outside of central business districts or airports (or in some cases train stations). Beyond discrimination, pre-booked services prevent cruising for passengers, which is inefficient travel and wasteful for all involved outside of a few dense areas. Dispatched services are either operated as a first-call, first-served system where taxi cabs are sent as needed, or as a scheduled service.

Shared Vehicles

Most taxicabs are limited to transferring one set of passengers at a time. Perhaps a group of friends will share a ride and end up at multiple destinations, but multiple pick-ups are not allowed. There is a special group of taxi licenses that does allow for shared vehicles in some cities, and shared taxis are often encouraged in the wake of major disruption to conventional transit services. For instance, in the aftermath of Hurricane Sandy in October 2012, which knocked out parts of New York’s subway system for over a week, shared taxis and jitneys were indispensable for maintaining mobility within the city.

Many cities regulate how multiple passengers are treated by the fare. Some cities allow for a separate charge for each additional passenger while others require a single fare for each trip. For passengers, being able to split the fare is a way to reduce the cost of taxi rides and may induce additional taxi trip making. Splitting taxi fares is common when taxicabs are used for social occasions more than for commuting or airport transfers.

Microtransit

Microtransit is a separate but similar category from shared vehicles, and part of a broader category of Mobility on Demand (MOD). Microtransit is defined by the use of smart phone apps through which riders request rides from vehicles that range in size from large SUVs to small buses (Shaheen and Cohen, 2019). The services are multipassenger, and typically dynamically routed based on passenger demand, though in some instances there have been microtransit programs with designated stops. Designated stops increase travel time reliability and simplify routing, but decrease convenience to riders.

Regulatory Frameworks

Limits to Entry

License requirements that limit the total number of for hire vehicles allowed are very common in cities throughout the world. Ostensibly, regulators seek to determine the optimal number of taxicabs for perceived and real demand, then set the limits accordingly. Yet, in practice, it is extremely difficult to know how many taxicabs are actually required for any given demand, and by maintaining an artificial ceiling in the number of vehicles allowed actual demand is not revealed. Rather rider demand with regard to the constraints of the number of available taxis and the costs of the fares are revealed.

The iconic New York City yellow cabs, for instance, are limited to about 13,500 medallions. The Haas act of 1937 initially placed a cap on the number of allowed franchises in order to mitigate the negative effects of the “taxi wars.” Too many cars searching for fares reduced the earning potential of drivers where fares did not cover costs and the competition for passengers actually reduced service quality and made passengers and operators worse off. Under the medallion system, each licensed yellow cab is required to have a physical shield, about the size of a grapefruit, stamped on the hood of the vehicle. Medallions in New York City grant the right to the holder to cruise for hails anywhere in the city as well as protection from price competition (fares are set by the Taxi and Limousine Commission of New York City). This experience is typical for cities around the world, and there have long been ebbs and flows about the proper number of medallions. In the United States, however, there has been no correlation between the number of taxi licenses and population size (King et al., 2012).

Fares

Taxi fares are regulated to ensure adequate earnings to cover wages and operating costs as well as to protect passengers from fraudulent behavior. Taxi services are a well-used example of credence goods. Credence goods are economic goods with asymmetric information and potential for fraud. Auto mechanics and physicians are also common examples. Credence goods rely on the seller to be credible as the buyer has little way of knowing the true value of the good or service being providing. While everybody knows that they should receive a second opinion when a doctor provides a diagnosis, soliciting competing bids for taxi travel is impractical for all parties. Regulated fares avoid the problems with credence good by eliminated the need for negotiation. This not only serves the customers well, it speeds up the process of hiring a cab since the amount to be paid is not haggled over on each trip.

Part of fare policy is the fare media used for payments. While taxicabs now nearly universally accept credit cards, cash is allowed. For ridehailing and microtransit, payment is typically through the app, which requires access to a credit card. Access to credit cards is problematic for households without bank accounts, who generally pay for taxis and transit with cash (King and Saldarriaga, 2017). Unbanked households may be low income and unbanked by choice, or perhaps undocumented immigrants who are unable to open an account. As new technologies foster payments through credit cards, access to such cards becomes an issue of equity.

There are also issues of integration between taxi, ridehailing and microtransit apps with public transit and mapping apps. Mapping services such as Google Maps seek to provide complete information for travel choices when queried for directions. Transit agencies also want to act as a clearinghouse for all transport options. Some service providers seek to standardize transactional data specifications so that on-demand trip requests can be traded among service providers similar to how airline booking works (Larsen et al., 2019). Allowing for trip trading could foster many firms servicing trip requests and improve overall service, but at the expense of individual firms keeping their clients within their own system.

Public Safety

Public safety is the key consideration for regulators. Many transportation scholars and economists argue that taxicab regulations should be limited to those that ensure public safety, but even with safety there is substantial disagreement as to what is required. The bare minimum regulation requires that all taxicabs and drivers have adequate insurance and licenses. With the apps that new firms use to match drivers and passengers, concerns about personal safety have been minimized through the argument that drivers and passengers are known to each other and the companies, which is a deterrent to harassment or crime. There are reported stories that

dispute this, and while overall taxi and microtransit services are safe, there are real concerns about behavior. This is especially true for shared rides, where the drivers may be required to keep the peace.

Another aspect of safety is shift lengths. With conventional taxis, shifts are fairly well defined. Where the driver is working their own schedule through an app, it is difficult to assess how long they have been on the road. Most driving occupations have limits on consecutive hours a driver can work. With gig work, where drivers may turn the apps on and off per their own preferences, these requirements are difficult to enforce. Maintaining healthy drivers who operate safely is an area of interest for regulators.

Vehicle Requirements

New York City is famous for yellow cabs, and London is equally famous for black cars. These are iconic aspects of the cities by design. Cities recognize the value of distinctive colors and shapes of valuable taxi services. New York's yellow cabs have inspired cities across the globe to adopt similar shades of yellow to mark their official taxicabs. By signaling through vehicle standardization, passengers are assured of a safe trip for the stated fare.

Vehicle age is also regulated. In New York City, taxicabs must be replaced after three years. Prior to Chicago changing its regulations, many old New York taxis became new Chicago taxis. (The market for used New York City taxis also partially explains why other cities have many yellow taxis.) While in service most cities require regular inspections of the vehicles to ensure safety.

Less common than vehicle age, color, or propulsion are strict requirements for the specific make of taxicab. Most cities have guidelines for what cars can be used, places such as London and New York go further in requiring a particular model of car. Uber and other ridehailing firms have some standards about what types of cars can be used by drivers on their platforms, though these vary by location.

Economics of Taxi Markets

Labor

Labor concerns are prevalent in taxicab regulation. Unregulated taxi markets are subject to intense competition that drives down costs and profits. Unfortunately for taxi and ridehailing drivers, their wages are the only part of the cost of doing business that are not fixed. Cars, insurance and gas are all exogenously priced and there is little ability to reduce these costs. Wages, however, can get squeezed to the point where taxi driving is no longer sustainable. While this is exactly how the market economy works, the challenge for taxicabs is the process of reaching equilibrium. Passengers who depend on taxis and cities that rely on taxis to complement their transit systems cannot afford to go through periods of over and under supply of taxis. This is one reason why cities attempt to limit the number of licenses.

Currently, the employment model of ridehailing companies (e.g., Uber) is under legal challenges in cities throughout the world. Many cities, states, and provinces have sued to force the classification of drivers as employees rather than independent contractors. The outcome of these legal challenges is unknown at the time of this writing, so details will be omitted. However, classification of drivers as employees would substantially increase the costs of business for these companies, and would affect the overall market for these services.

For microtransit, labor may be from direct employees or the driver is paid as a percentage of fares. Major ridehailing firms have developed pooled ride services where drivers are paid a share of each fare. Other private transit providers, such as Bridj or Chariot, have developed services where drivers are paid as employees. None of these attempts at private microtransit have proved widely successful, and the private transit operators have either gone out of business or only license their software at this point. In some places, transit agencies have been experimenting with microtransit as part of their overall services. The Kansas City Area Transportation Authority has been experimenting with microtransit since 2016, and currently offers a mix of on-demand services that include taxis, ridehailing and microtransit.

Usage

The advent of ridehailing services such as Uber and Lyft have expanded for-hire vehicle travel beyond traditional taxi markets. The 2017 National Household Travel Survey (NHTS) was the first large travel survey to ask about these new services. Since ridehailing firms are private, getting reliable data about usage has been challenging. From the introduction of Uber in 2009 to 2017, the for-hire vehicle market share doubled in the United States. For-hire vehicles might account for only 0.5% of all trips, but the percentage of all Americans who use ridehailing in any given month is nearly 10%. The growth trend has been greater in mid-sized and large cities, and among younger individuals and wealthier households (Conway et al., 2018).

There is substantial interest in using taxis, ridehailing and microtransit as a first mile/last mile service to bring potential riders to transit stations. While there have been many highly publicized pilot projects testing this idea, the evidence that these services are used for first mile access is weak (King et al., 2020). At issue is these services are a premium service, with high marginal costs through fares. As transit riders are sensitive to fare costs, additional costs of a taxi or microtransit fare inhibits transit use. In addition, first mile access represents a transfer, and how well such transfers are timed will affect use. Without subsidy to the user, there is little reason to think that these services will be widely used for first mile access to transit.

Microtransit

A lot of the interest in microtransit stems from historical observations about the role of jitneys in urban transport. Jitneys have long operated in the space between sanctioned public transportation and the private automobile. Jitneys take many forms: vans, cars, shared-taxis, minibuses, buses, and even motorcycles; and operated in numerous ways: semi-fixed routes, fixed routes with variable stops, and complete passenger control over pick-ups and drop-offs. In many cities, such as New York and Miami, modern day jitneys (known as Dollar Vans in New York) serve largely immigrant communities. Yet the jump from informal transit to formal systems is difficult and often fails (King and Goldwyn, 2014).

Micromobility Markets

Micromobility is a transit service that is ripe with promise but not yet with a clear market. As most entrants into microtransit have been private firms with the hopes of finding a path to profitability, most microtransit initiatives have proven more challenging than expected. Early private leaders in generating microtransit interest have gone out of business. When the Kansas City Area Transportation Authority piloted a partnership with Bridj in 2016, they served less than 1500 people in the first year. The challenge for microtransit is that it is very difficult to scale the business to something that can be profitable in many markets. The early success of companies like Chariot was that they kept their operations small, limited to a few routes. This limited market for microtransit certainly exists, but there is not yet evidence that microtransit can expand the transit market to the degree that ridehailing has expanded the taxi market.

Mobility as a Service

One aspect of microtransit that has received substantial attention is the idea of Mobility-as-a-Service (MaaS). In this form, microtransit is one part of the suite of services that a MaaS operator might offer. The appeal of MaaS is that by combining multiple potential modes of travel, riders are offered a suite of services that collectively offer a substitute to the utility of cars. There have been limited interventions of MaaS, mostly in Europe, and while popular with small groups of people these apps and services have not yet gained widespread use (Zipper, 2020).

Ultimately, the challenges facing taxis, ridehailing and microtransit come down to finding a business model that is profitable. Microtransit and ridehailing are yet to find a profitable market-based approach to new services. Partnerships with cities and transit agencies remain a promising way forward to improve services and reduce public costs, but this is a substantially different approach than what has been tried to date.

Conclusions

Taxicabs are an important urban transport mode that has received new attention with the advent of smart phone apps. Also due to smart phones and new location technologies, microtransit has garnered interest as modern jitneys. While taxis and ridehailing have expanded the user base over the past decade, experiments with microtransit have been inconclusive for their overall impact.

As a locally regulated transportation system that requires very little public outlay to develop, taxicabs and microtransit represent an important opportunity to improve transportation choices for all people. As researchers work with the wealth of new digital data from these services, patterns of usage and demand are being revealed that help policymakers engage with urban transport planning and policy with better knowledge and improved understanding of how on-demand mobility options help people navigate the city.

Regulators must deal with economic concerns of rent seeking and asymmetric information, plus complicated issues surrounding labor. As private operators, taxi drivers typically earn less than unionized transit workers and have limited ability to raise fares. Yet in many markets, taxicabs are a useful stepping stone for immigrants and low skill workers. Regulators must balance the needs of the drivers and operators with the broader public.

Lastly, taxicabs and microtransit are unlikely to succeed without public assistance, either through direct subsidies or regulations. Regulations can limit competition and ensure profitability. Direct subsidies can help travelers who need new options for daily travel live without a car, or can help transport vulnerable people with high quality service in the event that they need it. Fixed-route transit is critical for cities, but not the appropriate response to many transportation problems. Taxis and microtransit can potentially help fill these gaps, but are unlikely to do so if they are developed solely as private services that are limited in scale and scope.

Introduction

Mobility is a necessity and enables people to take advantage of the city amenities, thereby fulfilling a variety of needs (Bertolini, 2012). However, mobility can also have negative effects, such as congestion, traffic injuries, urban sprawl, air pollution and climate change. Traffic congestion usually appears when many people want to go to the same destination, at the same time and generally using less sustainable transport modes, such as cars. Those effects, known as transport externalities, have a negative influence on the quality of urban life. When talking about quality of life in cities, the most common dark spot is traffic congestion and the amount of time spent in traffic. Consequently, in urban transport, it is not the travel itself that is important to people but rather what travel allows them to do. Human activities respond to a variety of needs and wishes: residing, working, studying, enjoyment, social interaction, and also mobility. The spatial location of these activities will define travel patterns, generating/ attracting more or less trips, long or short, of people and goods. The number of trips is related to the household characteristics and land-use configurations, and its location within the urban area. The activities need different mobility levels and its relationship with transport is reflected in its spatial organization. In turn, the spatial interaction depends on the intensity of movements between the locations where activities take place.

Economic activities are produced, managed or administrated by companies, which are at different locations. In the same way, residential activities are produced by households. The spatial organization allows companies and households to make use of the differences between spatial locations to satisfy a variety of performance needs. For example, a company might need a lot of land and labor, so it would look for locations where the land is cheaper. Another company might concentrate high-quality facilities and qualified employees. Regarding households, decisions with respect to location of residence are a function of a wide range of attributes, valued in different ways according to household characteristics, where usually a trade-off between housing and transport costs is present.

However, all cities are different and within each city there are differences. There are rich and poor cities, with high or low accessibility levels, with different needs, where there are producers and consumers, jobs and households. The fragmentation of production and consumption, and the specific location characteristics of activities, generate large flows of people, goods and information.

Although each city has different mobility needs and uses different ways of satisfying them, in general all cities have something in common: activity concentration areas that produce/attract the most trips, are the most important factors that make up the organization of urban space. Then, the development of cities is conditioned by land-use and transport systems, from public transport to cars; the transport system has contributed to the creation of land-use patterns. Moreover, at the same time, the activity types condition the travel behavior and the transport system use.

Therefore, a balance of activity location, vocation and intensity is necessary for maintaining the correct functioning of the urban environment. To create or improve a livable urban environment, the requirements of human activities have to be balanced against each other. These requirements and decisions are directly linked to mobility. One of those effects is the modal share. This will depend on the distance, cost, travel purpose, and also, the travelers/employers characteristics. Generally, travel costs and travel purposes depend on land-use patterns. This relationship, where trip and location decisions co-determine each other, reveals the need for coordinated land-use and transport planning. There is a growing interest in the connection between land-use and transport all around the world. This is an essential component in transport policy and planning, aimed at creating more sustainable development across urban areas in the world.

Basic Concepts

Conventional transport planning gave way to the integration of land-use and transport planning, based on the principle that mobility needs should be met considering the land-use configuration, in order to reduce travel distances and offer better options for use of sustainable transport modes. Land-use and transport planning is a complex task since it covers various aspects related to changes in travel demand and land-use patterns at different scales (time and space).

Land-use and transport planning is an interdisciplinary field that works under a framework that includes political, socioeconomic, cultural and technological changes, where many concepts are used. Land-use encloses several subsystems such as physical infrastructure, workplaces, residences, land as well as the outcome of a complex urban real-estate market. Therefore, land-use planning serves the process of balancing competing demands on scarce urban land. On the other hand, transport, in addition to facilities, includes road capacity, public transport services, frequency and reliability, travel time and costs, and the resulting flows of people and goods. Transport planning is a process to design and improve the provision, operation and management of facilities and services for the transport modes to achieve sustainable mobility.

The theoretical impacts of land-uses on travel patterns basically depend on three principal dimensions, known as 3Ds: density (population, jobs), diversity (land-use mix), and urban/neighborhood/street design (Cervero and Kockelman, 1997). Urban areas with high densities, shops and services, well mixed land-uses, and nonmotorized-friendly designs encourage the use of sustainable transport modes. On the other hand, the impact of transport on land-use is measured in the accessibility of a zone: high accessibility levels increases the attractiveness of a location, which in turn, encourages urban development. Therefore, the land-use developments basically depend on accessibility, which is given by the transport system. Focusing on passenger transport, accessibility can be defined as the extent to which land-use and transport system enable people to reach activities (destinations) by a combination of transport modes (Geurs and van Wee, 2004). This approach shows there is a relationship between the land-use and transport systems.

Beyond land-use and transport planning as isolated disciplines, this integration has a large potential to influence mode choice and reduce travel demand on motorized transport modes, and is a key element to achieve urban sustainability. Within an institutional framework, laws, and regulations, land-use and transport planning is a field of research and practice that supports and informs decision-making and policy evaluation, activity location and accessibility improvements, which can (should) change over time.

Integrating the Land-Use and Transport Systems

The integration of planning is important because urban land-use and transport are directly related as was mentioned before. In addition, the impacts of transport on land-use happen at different time scales, and are measured through changes in the accessibility of a location. When land-use changes (function, intensity), there are also changes in human activities and in passenger and good flows, which also change accessibility levels. Accessibility is shaped by transport system infrastructure (supply, capacity and connectivity), which is not uniform across the territory.

For instance, the construction of transport infrastructure (public transport station, intermodal transport hub, road interchange) will generate an improvement in the accessibility, modifying travel patterns. This will also favor the concentration of residential or economic activities, which will generate new travel demand, and probably a change in land prices. This change in the urban structure depends on how much accessibility is improved, the increase in the supply of services and goods given by the transport improvement, the urban regulation, and of course, the local economic conditions. These processes will favor the location of new activities and a reorganization of the urban spatial structure.

Accordingly, land-use and transport planning are the main components of a dynamic feedback system and must be a coordinated process. This concept can be summarized as follows (Wegener and Fuerst, 2004):

- The land-use diversity (residential, services, commerce, industrial) over the urban area determines the locations of human activities such as residing, studying, leisure, or working.
- The distribution of the different human activities in space requires spatial interactions between zones in the transport system to overcome the distance between trip origins and destinations.
- The distribution of infrastructure in the transport system creates opportunities for spatial interactions and can be measured in terms of accessibility.
- The distribution of accessibility in space codetermines location decisions. This will result in changes of the land-use system. The cycle continues.

This feedback cycle is explained by the solid arrows in Fig. 1. As shown, the transport system has a direct effect on accessibility, which is not uniform. Then, accessibility slowly influences land-use patterns: the construction and development of workplaces and housing increases gradually and depends on other variables such as the economic and regulatory context. In the same way, the effects of human activities on transport infrastructure is quite slow, since transport networks are the most permanent elements of the physical structure of cities. Finally, the location of human activities in the land-use system gives rise to a demand for spatial interaction in the form of people or goods transport. These interactions can adjust in a matter of days or hours due to congestion or travel demand changes.

Figure 1 Land-use and transport feedback cycle. Source: adapted from Wegener and Fuerst (2004) and Bertolini (2012).

This reciprocal relationship is co-determined by external factors (dashed arrows in Fig. 1). For instance, the development of transport systems is not only determined by the travel demand but also by regulations, funding, technological innovation, and mobility policies. Land-use developments depend also on the city regulations, availability of land, real-estate market, environmental conditions and land-use policies. In addition, preferences for households and companies play an important role in the urban development process. Finally, besides land-use and transport systems, temporal component of accessibility is a key element for people since it includes the availability of opportunities at different times of the day, and the time available for travelers to participate in certain activities. The individual component of accessibility, reflects the needs (sociodemographic characteristics), abilities (physical condition, transport supply), opportunities (socioeconomic characteristics) (Geurs and van Wee, 2004), and capabilities of people (Cao and Hickman, 2019).

Although this definition is simple and easy to understand, the mechanisms through which the feedback cycle interacts between systems has been difficult to isolate and measure empirically, mainly because the complex interactions among several forces beyond the observed structure of the land-use and transport systems (Acheampong and Silva, 2015). Despite these important nuances, the land-use and transport feedback cycle provides a useful framework for planning and evaluates principles aiming at supporting sustainable transport modes at different levels. Sustainable land-use and transport planning require a deep knowledge of the urban and regional area, and a clear idea of the policy objectives.

Future Land-Use and Transport Challenges

Although several studies have concluded that urban structural variables (e.g., 3 Ds) have statistically significant influence on travel behavior, the results of other studies of different cities are sometimes inconsistent (Zhang et al., 2019). Despite this, there is still a consensus about the influence of activity locations, densities and the land-use mix on transport demand and travel patterns. These discrepancies may be due to diversity of urban environments and cultures, and should be studied in detail. The challenge is also to reconcile the short-term effects and long-term ones (Kasraian et al., 2016).

Land-use and transport planning is essential for well-informed decision making processes in urban environments. However, to help local authorities build appropriate plans that consider this dynamic feedback, and therefore improve policies' effects on city livability and reach sustainability goals, land-use and transport planning must try to bridge the gap between research and practice. First, city plans reflect a concern with accessibility in one way or another, but few explicitly articulate the relationship between land-use and transport systems over time and its side effects. Second, the proliferation of activity-based travel demand models, many times using big data sources, sometimes present difficulties in their integration with land-use models at disaggregated level. Third, the research and practice are different according to the region. The urban challenges of the cities in the Global North are considerably different from those in the Global South. Here is where most of the world's population reside, and cities in the Global South are characterized by rapid growth in population, motorization and urban footprint, without proper planning and control instruments. Integrated planning in these cities is crucial, but also the data collection and the development of evaluation tools. Therefore, operational land-use transport interaction (LUTI) models that recognize data limitations should be implemented, particularly in

Global South cities, mitigating existing knowledge gaps to improve urban planning in practice. Moreover, due to the high cost of urban infrastructure, it is necessary to incorporate concepts, methodologies and instruments of land value capture and pricing measures for private transport.

In addition, the current capabilities of the current models need to integrate complementary analysis, such as energy consumption, environment, health, or equity. With respect to integrating forecasting of possible impact of urban policies in the future, it is necessary to incorporate uncertainty explicitly into the land use and transport planning process. Cities change, and when the decision making involves long term decisions, the level of uncertainty, can be particularly high. Further research is needed to understand uncertainty over time and across different contexts and to develop and apply new methodologies to handle these challenges. Urban policies may also affect other levels, such as spatial and economic spillovers. Despite the great advances in recent years, big challenges still remain for land-use and transport modeling and their application (Moeckel et al., 2018).

In respect to the analysis of planning results, many tools/process can favor solutions that produce the greatest aggregate social benefit. This can hide large inequalities within local territories. A great mobility system is not sufficient to achieve sustainable development, including the reduction of inequality gaps. Sustainable long-term urban planning is essential, balancing accessibility and location with even distributions.

Finally, it is necessary to overcome spatial barriers for social, education and economic activities through an inclusive transport system. An initial step must be education: if students are taught to think on land-use and transport issues as an inseparable bundle with a dynamic relationship, mobility and land-use development issues will be one and the same.

Implications for Urban Planning Research and Practice

The landscape imposes certain conditions on urban development and therefore on the activities organization. As seen, the transport system influences the land uses and in turn, the land uses influence travel patterns. The combination of activities and accessibility constitute the local attractiveness of an area, which in the long-term determines the land use pattern and ultimately its urban form. This two-way interaction can be quantified from the perspective of location and mobility. The spatial location of the transport system is a central component of the definition of the spatial structure of a city. This system will allow activities to be carried out more or less easily (through improved accessibility). The scales of analysis, whether global, regional or local cannot be disregarded.

Reflections about the limitations of traditional approaches to urban planning, as isolated disciplines, are essential in the context of global development agendas that increasingly recognize the social implications for land-use and transport planning and its interaction with other areas of planning. Here, it is quite important to understand the importance and the changing role of urban transport in the modern world as a policy that can enable or hinder access to opportunities, services and goods that help build human, financial and social capital. That is, the integration of land use and transport planning is a key factor to improve the urban quality of life.

Consequently, land use and transport planning should aim to reduce the rate of growth of individual and motorized trips, supporting and encouraging use of public transport, walking and cycling, and balancing land use distribution. In order to achieve sustainable urban development, land use and transport planning goals have to be in line with the global challenges such as those related to poverty, inequality, climate change, environmental and social justice. Then, the following principles for successful land use and transport policies can be summarized in (Wegener and Fuerst, 2004):

1. Basic criteria of sustainable mobility and land use are only successful if the use of the private vehicle (car/motorcycle) is less attractive; that is, more slower or expensive (in the short term). Assuming that driving must be cheap is incorrect.
2. Land use policies to encourage the 3Ds without ancillary measures that make private vehicle use less attractive, will have a limited effect as people will continue to make longer trips to maximize their opportunities within their travel time and travel costs budgets. However, these policies are important in the long term as they provide the future conditions for a less private transport dependent urban lifestyle.
3. Pricing measures aiming to make private vehicles less attractive are very effective in the short term to reduce distances and travel times, as well as their modal share. However, effectiveness depends on a spatial structure that is not very dispersed.
4. Fears that land use and transport measures oriented to limiting private vehicles use in urban centers (including pedestrianization) are detrimental to the economic viability of these areas are baseless.
5. Policies aiming to improve public transport and encourage its use, in general do not lead to a significant reduction in private vehicle use, unless they are accompanied by other complementary measures.

Considering accessibility as a structural axis in the discussion about urban policies can enable integral land use and transport planning and evaluation of urban systems. This is possible as integrated planning forces planners, practitioners and decision makers to consider the interaction between its different components and highlights conditions of vulnerability and inequality within the territory. Furthermore, an integral vision of this relationship in its different scales and temporal dynamism can account for possible side effects of urban policies. For instance, if current practices in land use and transport planning are greatly improved, incentives for urban expansion may not be generated in the long term, and would lead to a potential balance in urban development. Therefore, if the ultimate goal of integrated land use and transport planning is constructing more sustainable cities, each strategy and instrument must contribute to one or more of the key policies, as shown in **Table 1**. Here, a high-level summary is provided, suggesting impacts

Table 1 A strategy contribution matrix

Key strategy element	Reducing the need for travel	Reducing car use	Improving public transport	Improving road network performance
Land-use	4	2	2	1
Infrastructure	–	2	5	3
Pricing	1	5	3	1
Attitudes	2	4	3	3
Management	1	2	4	5
Information	3	2	–	–

Minor contribution = 1; Major contribution = 5.

Source: May et al. (2005)

in which the different types of strategies can contribute to those in different categories. For instance, land use measures contribute most to reducing the overall need to travel in the long term, but pricing measures are the most effective way of reducing the level of private transport use in the short term. Other strategies can help to improve public transport and road network performance. The most important message is that there is no unique solution to urban problems: an efficient land use and transport planning practice must involve measures from many disciplines and sectors.

Integrated land use and transport policies have been promoted as a more realistic and effective approach to solving urban transport problems, rather than using isolated measures. With the integration of those two systems it will be easy to achieve greater performance from the overall urban policy. To make this a reality, the integration of different policy instruments involving land use planning measures, infrastructure provision, information, management and pricing must be taken into account. It is also necessary to integrate other policy sectors, such as environment and human health. The drawback is to understand how different packages of measures interact with each other: if they are a simple sum of effects, or there are synergies of some kind; and then identify the most successful combinations (May et al., 2006). This mix of effects has an impact on the spatial organization of cities over time.

Conclusion

The growing urbanization across the world has demonstrated that the urban environment and its land use and transport planning policies should be regarded as a crucial research topic more than ever before. When comparing land use and transport measures, latter measures are more direct and effective in achieving sustainable urban transport goals in the short term. Nevertheless, a support for long-term land use measures is essential for the development of more inclusive, safe, livable and less car dependent cities. In summary, integrated land use and transport planning, integrated with other relevant disciplines, are essential to achieve sustainable urban development.

Introduction

Car parking is a complex and problem rich area of study which encompasses issues relating to types of parking, availability, price, quality, different motivations for use (shoppers, leisure users, commuters, employers, and residents), different users (male/female, able bodied, or disabled) and the authorities who are tasked with managing this scarce resource as efficiently and effectively as possible with due consideration to land use planning, congestion, and the environmental impacts of private vehicle use (Ison and Mulley, 2014). When undertaking a journey by car, a parking space is required at the destination (and also possibly en-route in the case of a motorway service station or other intervening opportunity). In deciding where to park, cost, availability, and personal utility are all important in choosing not only where to park and the time to devote to the total journey, but also whether an alternative mode of travel is preferable to driving or indeed whether the journey is undertaken at all. This means that when developing a coherent parking policy there is a need to consider work, retail, leisure, education and residential parking, patterns of mobility, car ownership levels, the changing demographics, and mobility needs of the population, car ownership levels and the availability and frequency of public transport provision.

This chapter seeks to detail the types of car parking which are available as well as car parking management and workplace, retail, and residential parking considerations.

Types of Parking Space

Local authorities, private companies and, increasingly, residents (home-owners) provide and manage car parking spaces. Table 1 provides details of the types of parking which can be found in the majority of towns and cities worldwide.

Local authority on-street parking is parking on the roadside. Local authorities have direct control over it and as such can manage its supply or demand via the use of regulation and/or the price mechanism. Payment, where demanded, is usually made via a pay and display parking meter or (as is the case in many European and US cities) by phone.

Local authority off street surface or multistorey car parks refer to car parks that are not on the public road but that members of the public can utilize. Spaces are charged for either by means of pay and display machines or payment before exiting via a barrier system. There is normally a maximum period of stay and a sliding scale of pricing based on duration and the time of day or period of the week. Off-street parking of this type is readily available in towns and cities throughout Europe and North America (Rye and Koglin, 2014).

Privately owned public off street parking is available for public use and is charged for in the same way as local authority off-street parking is administered. It is increasingly common today to see payment through smart phones. This has the benefit of being *cashless* and has the dual advantage of aiding the motorist in that they do not have to carry cash in order to make payment (which often requires the correct amount) and the operator is spared the task of emptying the meters. It does, however, rely on good cellular network coverage and car drivers having a charged mobile telephone.

Private nonresidential parking is essentially off-street parking owned and controlled by a specific company or an office development. Spaces are often provided free for those associated with the organization and act as a perk of employment although charged spaces are increasingly common. This form of provision has been important both in terms of recruitment and retention of staff (Marsden, 2014). Supply of this type of parking space has its origins in planning regulations with developers being required to supply adequate provision for the size of development. This has, however, been seriously curtailed, in the UK at least, via restricting planning consent which seeks to restrict car parking spaces and encourage public transport use. The workplace parking levy (WPL)

Table 1 Types of car parking spaces

<i>Ownership</i>	<i>On or Off-street</i>	<i>User</i>	<i>Charging mechanism</i>
Local authority	On street [roadside] Off street	General Public General Public [surface or multistorey car parks]	Charged and free Mostly charged but can be free
Privately owned	Off street	Public	Charged
	Off street	Private nonresidential parking	Free
	Off street	Residents	Free (although some residents are now renting out parking spaces on their residential driveways)

Source: Adapted from Ison (2014).

has been advocated as a means of dealing with the issue of private nonresidential parking spaces. This is covered in more detail in a later section.

Residential parking essentially refers to spaces which are associated with privately owned houses and flats. While historically it was only residents who used such spaces there has been a growing trend in recent years for these spaces to be made available for use by nonresidents, particularly in locations near major generators of traffic such as hospitals, universities, and large sports stadia. This phenomenon will be dealt with in more detail below.

Parking Management

Bates and Leibling (2012) estimate that, on an average a car spends approximately 80% of its time parked at its owner's address, between 3% and 4% being driven and 16% parked at a point of destination be that work, retail, leisure, or education related. The 3%-4% could be spent in a congested urban environment with the social costs that entails, thus requiring some form of *demand management* while the 16% will most probably be in an urban area taking up valuable space that could be used more productively. This supports the view that the notion of "free parking" does not exist (Shoup, 2005).

Parking management, namely policies aimed at a more efficient use of scarce parking spaces, is required as part of a package of transport demand management measures to avoid the anarchic situation evidenced in many mega cities world-wide with hyper-congestion, environmental degradation, safety and health issues. As stated by the UK House of Commons Transport Committee (2013 p.5) "Effective parking strategies help to reconcile the competing demands of different road users. Parking restrictions are used to manage congestion and ensure that there is clear and fair access to public roads. The enforcement of parking restrictions should help to ensure that the needs of residents, shops, and businesses are met. Local authorities have primary responsibility for setting parking policy and enforcement strategies on local roads." Parking management can:

- encompass policies that lead to a more efficient use of parking resource;
- be an effective measure to reduce the level of traffic and its associated emissions;
- encourage motorists to utilize modes other than driving alone;
- form part of a "package" of transport measures; and
- be used as a demand management measure.

While parking management has been used extensively by local authorities in tackling congestion and localized air pollution it is often perceived as a second best measure when compared to congestion pricing which charges directly for the road space being used. In saying this, it has been a much easier approach to implement given its broader public appeal than say road pricing although there is often policy conflict between it being a demand management measure and its revenue generating capability and its impact on the local economy. Parking management can often be seen as reactive addressing an issue when it becomes evident such as commuters parking in residential streets.

Rye and Koglin (2014) detail the reasons for enacting parking management policies, namely:

- In certain localities there is inadequate or underutilized parking supply;
- There is competing demand for parking spaces from commuters, residents, and leisure users;
- This competing demand is likely to result in *parking search* (or cruising) as vehicles drive around searching for a parking space;
- In certain localities, most notably older- city centers containing terraced housing, there is a lack of supply, requiring the enactment of some form of permit system as a means of allocating demand;
- The issue of monitoring and enforcement of parking controls;
- Badly parked vehicles can result in safety issues and can impede access by emergency services vehicles.

The management of parking can take a number of forms depending on which type of parking is being considered, whether it is on-street or off-street. On-street parking management is in many cases the easiest to control either via the regulatory process by the use of double yellow lines (which, in the UK, denote the prohibition of on-street parking) or the pricing mechanism by the installation of parking meters which oblige drivers to purchase a ticket from a road side machine. This involves payments by cash,

card or mobile phone with drivers required to input their number plates to prevent loss of revenue when tickets are transferred between vehicles.

The introduction of double yellow lines and equivalent road markings has the dual effect of freeing up road capacity and also restricting the number of termination points at a destination. There is however, a downside to this approach. Limiting the number of spaces can lead to an increase in search time which clearly has an opportunity cost but also has the potential to increase the level of congestion and air pollution in the area where regulations are in place. In addition, there is the likelihood of encouraging through traffic since the supply of termination points has been curtailed and the road network freed up.

Technological solutions can also be used to enhance the efficient use of parking spaces so as to meet demand and also reduce parking search. One such solution is SF Park used in San Francisco in which sensors are embedded in on-street parking spaces in particular locations so that real-time availability of each space can be monitored and those seeking a space made aware of the fact that availability and dynamic pricing charges have been enacted as a means of reconciling demand with supply.

The use of parking meters can be configured so that the number of long stay spaces is reduced and that of short stay increased. This will have the effect of reducing the number of commuter journeys while increasing availability for shoppers and leisure users and also encouraging the turnover of spaces.

Another form of restraint involves what is known as *Controlled Parking Zones* (CPZ) where preference is afforded to local residents who purchase an annual permit allowing them to park in a particular zone. This is usually in areas where demand outstrips supply, most notably where there is a high proportion of terraced housing and in locations subject to excessive on-street commuter parking. In almost all cases, dedicated spaces are specifically demarcated and reserved for the use of disabled motorists (irrespective of whether they are the driver or a passenger). In the EU, these spaces are reserved for use by vehicles displaying a Blue Badge which has been authorized by the local authority due to specific health or mobility needs.

Parking at the Workplace

In terms of managing parking, one of the main issues is parking at the workplace and whether this can be controlled by the organization themselves or by the local authority.

Parking Charge at the Workplace

Employers may seek to implement a site-based parking management policy-based on the use of permits, which can either be issued free or charged for. Seeking to implement a site-based policy may be based on a number of factors namely:

- The site location is constrained, possibly in an urban area as is the case with many hospitals and universities both being significant generators of traffic but with limited availability of land for parking.
- Congestion maybe an issue both in and around the constrained site and on the radial routes used to access the site.
- Parking management is included as part of the companies travel plan.

As with any measure of this kind employee acceptance is a key issue. Questions raised when such a measure is being considered/implemented include the availability of alternative modes of transport, not least in respect to public transport and its frequency and reliability in peak commuter periods, and if a parking charge is in operation is it perceived as being fair and equitable. In terms of fairness and equity a number of organizations have linked their employee parking charge to their vehicle emissions and salary grade, in that the higher their vehicle emissions and their salary grade then the higher the parking charge they pay. As for occasional staff users a book of vouchers based on some proportion of the cost of a full permit might be issued. Visitors could be subject to a pay-and-display system with, say, the first 30 min free, 2 h and beyond charged with an increasing fee.

Workplace Parking Levy

One of the issues faced in relation to parking management is the issue of private nonresidential parking spaces, that is, office spaces provided by organizations for their employees which the authorities have limited ability to control directly. As a result, there is ongoing interest in the WPL which is a scheme designed to charge employers a levy for the number of parking spaces they have available on their site. The WPL was first proposed in the UK in 1998 as part of the Government's White Paper on the Future of Transport: A New Deal for Transport Better for Everyone. In the UK, the Government subsequently gave power to local authorities to implement a WPL with the proviso that the revenue was hypothecated for transport improvements. To date only Nottingham has implemented such a charge in the UK but other cities most notably Bristol, Edinburgh, Glasgow, Leicester and Reading plus the London Boroughs of Camden and Hounslow are, at the time of writing, showing interest. The WPL scheme is based on the notion of charging employers for each parking space they provide for their employees above a certain number. A dedicated chapter is available on the topic of the WPL, focusing on the Nottingham scheme, so the following offers only a short bullet point introduction.

- The Nottingham WPL was fully implemented in April 2012 and is currently the only WPL scheme in existence in the UK;
- The objectives for the Nottingham scheme are to:
 - address the issue of congestion through encouraging employers to reduce their number of parking spaces [and thus their WPL bill] and as such limit the number of parking destination points for motorists;

- use the hypothecated revenue raised from the WPL to secure “high quality sustainable public transport” that offers realistic alternatives to the private car;
- assist business in developing “smarter travel choices” as part of dedicated travel plans;
- have no significant impact on business investment decisions in the city;
- create no significant displaced parking issues;
- The main driver for opting for the WPL option in Nottingham was to enable a quicker income stream generation than would have been possible if a road pricing scheme had been introduced. A stream required so as to part fund the new tram line infrastructure development;
- Those employers providing 10 or more employee parking spaces are levied per space annually.

Retail Parking

Historically large out of town shopping developments have been a feature of retail activity particularly in the UK and US. Such locations have tended to offer free parking on a large scale. It is clear that with the advent of on-line Internet shopping companies such as Amazon are having a significant impact on the demand for this type of retail experience. As such land used for this purpose is likely to change being made available for redevelopment such as housing use.

In addition, the traditional high street is being significantly affected by on-line shopping and the change of purchasing habits. Thus parking associated with retail shopping in town and city centers and the pricing of those spaces is increasingly being called into question as ways are being sought to halt the decline in high street footfall. A related issue with respect to parking provision in urban areas is that of multistorey car parks. In many instances this comprises ageing infrastructure in need of replacement or retrofit. In addition, the users are increasingly being identified as an ageing population with a range of disabilities.

Residential Parking

There has been a growing world-wide trend in recent years for private accommodation, namely houses and flats to hire out their off-street parking spaces for use by nonresidents in certain locations. This unregulated residential car parking provision has emerged in recent years and forms an online virtual parking marketplace. This has involved residents seeking to address the needs of those motorists wanting to park, the cost of that parking and the lack of available car parking spaces around major generators of private motor vehicle traffic be that in the vicinity of airports, hospitals, or major sporting events. On-line parking spaces are accessed via websites which seek to match individuals who want to rent out private spaces with drivers looking for somewhere to park their vehicles. The individual parking providers upload a profile detailing the location, type, and importantly the price of their parking space or spaces and motorists search for a suitable space by location/keyword.

The use of residential parking spaces offers the user a different product type which is normally cheaper, thus appealing, and also affords a personal service which could involve the user/s being dropped off, for example, at an airport, valeting the user's car whilst away or even looking after the customers dogs. As regards the provider then renting out what is usually an unused parking space is a relatively easy means of supplementing their income or in the case of those that are unemployed then their only source of income.

Clearly there are implications not least in that it could represent a challenge, in terms of competition to traditional providers, which could be a local authority or airport, it could lead to traffic congestion and safety issues as a result of inconsiderate parking and there are also security issues raised by leaving a vehicle in the driveway of what is essentially a strangers property (see [Budd et al., 2013](#)).

Conclusions

Parking is a complex and at times controversial topic not least since a change in one area has implications to other aspects of the system. It has an economic, political and technological dimension, is multifaceted and pervades all aspects of transport demand management. It is an area subject to incremental change such as the introduction of a CPZ which is more likely to gain public and political support than large step changes. Parking management, comprising the efficient utilization of an important resource, is a significant element of transport policy and extensively used by local authority planners and increasingly individual organizations as a means of addressing the issue of demand and supply and the related congestion and environmental implications. Parking controls and pricing decisions can be used widely as a means of managing urban transport and improving network traffic flows. As such, over time there has been an increase in on-street parking controls in the form of time restrictions or varied pricing tariffs in addition, to new initiatives such as the introduction of the WPL as a strategy aimed at managing parking.

There is a range of emerging issues associated with parking and parking management not least the:

- increased use of and role for technology most notably parking apps and schemes such as *SF Park*;
- ways in which the Internet has been used to stimulate the online virtual parking marketplace allowing for a new area of parking supply with the associated implications;

- changing nature of parking demand given the advent of on-line shopping and the associated decline of the high-street;
- sophisticated use of parking management at the organizational level;
- desire to impact on private nonresidential parking spaces via the introduction of the WPL and the associated hypothecation of the revenue raised.

One thing is certain and that is the field of parking is dynamic and will continue to change. For example, the advent of the autonomous vehicle is likely to negate the need for large areas of expensive land in urban area being devoted to car parking. As such, urban land use will most probably see significant reconfiguration.

Evolution of Passenger Transport Planning: In Search of Efficiency

The Urban Transport Planning (UTP) process is a formalized planning methodology designed specifically for assessing current and expected transport conditions in a city and developing and prioritizing strategies for their improvement in the short and long term. The core components of the process are transport system analysis and forecasting, land-use and urban development assessment and forecasting, and goals, policy, and plans formulation based on technical criteria (Dimitriou, 2013).

With the evolution of information technologies and an increasing ease to collect reliable data at larger scales for planning purposes, the UTP process became highly influenced by advances in demand modeling. In particular, the development of the four-step transport demand model, used for planning and assessment of transport projects up to this date, became a central driver of the evolution of the UTP Process. This model seeks to simulate and forecast travel conditions and estimate the effects of different interventions on transport demand. The model is concerned with the stages of decision making of the individual traveler. This is one of the aspects that has received the most attention from the academic and practitioner community since the development of the UTP process, to the extent that it is often mistaken with the UTP itself (Dimitriou, 2013).

The evolution of this model has been guided more by the refinement of the tools rather than a thorough conceptual debate (Bates, 2007). The coherence and compatibility between the unified framework for transport modeling and planning behind the four-step model and the economic theory of utility maximization, and supply-demand balance, as well as the rapid evolution of computing capabilities has allowed mainstream techniques to grow in scale as new and more complex problems can be addressed (Bates, 2000). Modern modeling techniques for four-step transport demand analyses depend largely on big data sets which allow for high statistical representativeness at different levels of aggregation (Ortuzar and Willumsen, 2011).

In comparison with the components of the four-step model, other techniques and submodels for urban development analysis and forecasting included in the UTP process have experienced a slower development despite early studies dating from the 1950s and 1960s (Dimitriou, 2013). This is the case of tools to analyze urban development and interactions of land-use and transport in the context of the UTP process that seek to provide inputs and feedback to traffic submodels. The complexity of these interactions and the still active debates in relation to the conceptual and practical implications of transport and land use models have inspired an important number of works and tool developments in this area. However, lack of consensus related to the best approach to transport and land-use modeling have “made theories and software almost inseparable” (Ortuzar and Willumsen, 2011, p. 493). Land-use based analysis and forecasting are almost as data intensive as the previously described four-step model of the UTP process. However, as with previous submodels, these models and analyses require assumptions on public and private sector policies, decision-making processes, and human behavior for their effectiveness (Dimitriou and Gakenheimer, 2011). The UTP has also adopted formal methodologies for comparing the intended and unintended effects of transport interventions over the years, such as Cost-benefit analysis (CBA).

Adoption and Development of the UTP in the Global South

Approaches to modern UTP initially developed in the United States of America and Europe were later adopted in countries of the global south during the 1970s and 1980s. This adoption was often facilitated by international development agencies. Such technical and technological transfer of transport planning approaches to developing countries have led to disenchantment with city-wide, long-range efforts at UTP. While most theories applied today in the global south for transport planning come directly or indirectly

from western models, the pillars, limitations and requirements of mobility, and accessibility in the urban south are substantially different from the context in which these theories and knowledge originated.

Although, geographical, economic, and even social elements play a significant role in current transport planning conducted under the UTP process, the overarching rule of technocratic approaches has governed not only the past evolution of transport planning in the industrialized world, but also the way it was transferred to, and further developed in the global south. Between the 1960s and 1980s the UTP process suffered significant changes in industrialized countries because of revised policy goals related to environmental and social sustainability, while the developing world saw countless applications of the process in its initial form. The formalization and widespread distribution of methodologies and frameworks for UTP in the developed world and the role of development organizations on urban development expedited international dialogue and adoption of the UTP in many cities of developing countries.

During the 1960s, pressing increases in demand for private motorized transport in developing cities led local governments to seek advice from international consultants. This led to methods from the early definitions of the UTP to be applied in developing countries with minor adaptation to the context of developing cities by consultants under limitations of time and resources imposed by their contracts. In the years that followed this initial technical transfer of approaches to UTP, various North American, European, and Japanese consulting firms started offering their expertise to developing countries at a larger scale, profiting from refinement in modeling techniques and increasing computing capabilities. These studies often led to transport master plans and guidelines for development later adopted by local practitioners (Cervero, 2013). In addition, influence from foreign and local construction companies profiting from infrastructure-centered plans contributed to the consolidation of ambitious transport plans aiming at reforming urban structures through large infrastructure investments with the aims of modernization, increasing economic output, and employment generation (Vasconcellos, 2014).

Financial aid and capacity building initiatives are inextricably influenced by policy priorities and dominant knowledge in the international agenda (Dimitriou, 2013). In this regard, increasing importance of the role of transport for development in the agenda of international aid agencies from the developed world in the 1970s sought to respond to the transport challenges of cities in the developing world. Increase in urban transport lending by the World Bank grew from US\$32 to US\$113 million per year for technical assistance and from 0 to US\$13.1 million for training between 1972 and mid-1980s. International cooperation missions focused primarily on preparing local practitioners and civil servants in transport to design and implement policies under the UTP. In addition, many studies funded with international development aid produced planning guidelines based on the UTP process for large and medium-sized cities in the developing world, which were later incorporated to requirements for qualifying for external and internal urban transport financing (Dimitriou and Gakenheimer, 2011).

International development agencies are not the only agents involved in the transfer of policies and planning practices to the Global south. Urban policy has circulated at increasing speed due to several factors leading to “fast policy”. Better transport and communication have enabled rapid visits to other cities and new forms of evaluation allow rapid engagements with other policies. Intermediation from institutions such as think tanks and consulting companies has grown considerably since the 1970s, which profit primarily from policy models they produce and circulate. Recent decades have witnessed a “triumph of politics over policy”, which have influenced policy turnover times aligning them with political cycles. Considering that automobile owners have traditionally been a powerful lobby in the developing world, this aided development of infrastructure-incentive and traffic-centered policies for a good part of the 1980s and 1990s.

Prescriptions from structural adjustment policies fostered investments in additional network capacity in the 1980s in search for improvements in economic performance (Dimitriou and Gakenheimer, 2011). These policies not only added to a rapid change in the structure of transport networks in developing cities, but also to the dissemination and adoption of transport modeling and design tools.

Although many limitations identified in early models for demand forecasting have been resolved throughout the years, higher model complexity has increased requirements for technical and financial resources to access such tools. This becomes a daunting challenge for the adoption of travel demand models in contexts where resources are limited, as well as a problem of coherence between evolving regulations seeking to incorporate better modeling in transport planning regulations and the capacity of local governments to finance, and make use of such information (Cervero, 2013; Dimitriou and Gakenheimer, 2011).

These priorities in conditions for development aid changed in the 1980s and 1990s, incorporating new concerns related to increasing efficiency of public transport. A policy paper published by the World Bank in 1986 for the transport sector, which included priorities for UTP in developing countries, stressed the need for efficient transport management, involvement of private sector, reduction in subsidies, and incentives to competition under a deregulation framework. This echoed the approaches to planning and policy development in many cities that had started to develop their own solutions to urban transport issues using local ingenuity and increased funding from both local and international sources (i.e., Curitiba, Bogotá, Mexico, Lagos, Bangkok).

Developments in the late 1990s and 2000s were more concerned with the issues of sustainability and incorporated some long-standing needs for capacity building, institutional strengthening and focus on public transport, and empowerment of nonmotorized alternatives. While significant changes in urban transport development were taking place in some cities of the global south, these did not influence significantly the framework for UTP and policy evaluation. Discussions on environmental sustainability following the oil crisis of the 1990s strengthened the need for sustainable transport development and focus on efficient mobility systems centered on public transport investments. These interventions aimed at using data from technical appraisals to forecast travel demand and design policy instruments that allowed efficient traffic management that reduced the environmental footprint of urban transport development. This shift in the planning logic marked the inclusion of more rigorous criteria of environmental appraisals in transport policies throughout the world and defined new conditions for local and international financing for infrastructure projects.

Challenges and Opportunities for Transport Planning in the Global South

Tools for transport planning have experienced continuous refinement in the last three decades, although modeling has been a central issue even in modern transport studies, which becomes a point of debate. The principles of rational choice and utility maximization that underpin most transport demand models can be considered as too narrow for reflecting the multiplicity of needs, preferences and drivers of transport users with different social identities, beliefs, and principles. The framework of the UTP has suffered relatively minor changes in its general structure despite incorporation of new concepts and methodologies in its different stages in the industrialized world. This is partly explained by shifts in policy priorities and emerging concerns in relation to inclusiveness and sustainability of transport, which have influenced from basic concepts governing transport modeling to tools for strengthening decision making approaches. However, such changes in policy objectives and priorities, as well as the widespread adoption of better-adapted forms of planning in global south cities are still challenged by rapid urbanization and population growth, the increasing dependency on car use, high degrees of poverty, social inequality, and weak institutions. These challenges can also often present opportunities of innovation and localized developments, which need to be acknowledged if the positive evolution of transport planning in global south cities is to continue.

Rapid Urbanization and Transition to Automobile Use

There is a strong correlation between urbanization, per capita income and motorization (Vasconcellos, 2014), which links economic development and its associated increases in purchasing power to the rise of individual mobility and motorization rates. Car ownership has grown rapidly in emerging economies such as China, India, Mexico, and Russia (Pojani and Stead, 2017). Increased use of private automobiles and motorcycles contributes to a substantial increase in traffic congestion and travel times. Various case studies also point to a rapid increase in traffic fatalities of air quality concerns. Such is the case of cities in Brazil, Nigeria, Vietnam, and Indonesia, while large Indian cities are some of the most polluted in the world.

While it is expected that increases in per capita GDP are accompanied by an increase in individual mobility and motorization rates, abundant evidence from industrialized countries shows that motorization rates reach peaks in ownership of private vehicles that remain constant despite further increases in purchasing power. Rates of around 600 vehicles per 1000 inhabitants are among the highest values recorded in these contexts.

Car and motorcycle ownership rates can be largely explained by income and population distribution. With the rise of the middle classes and the transition from low to middle income levels there is an expected increase in both automobiles and motorcycles in cities of the global south. Nonetheless, motorization rates in the global south are still low compared to industrialized countries. The number of cars per 1000 inhabitants varies from 55 in Ecuador, to 185 vehicles in Mexico. Countries in the lowest range of motorization rates such as Peru and Bolivia are between 51 and 56 cars per 1000 inhabitants. Asian cities are continuing to grow very rapidly. In many cities the number of vehicles is doubling every 5–7 years.

Evolution of the personal vehicles industry has led to increasingly affordable cars and motorcycles. The latter has a much lower income threshold for purchasing and daily operation, which has led to a rapid growth in motorcycle ownership. In Uruguay, the number of motorcycles per 1000 inhabitants reaches 141 vehicles, while in Brazil and Colombia this figure is 81 and 68, respectively (Hidalgo and Huizenga, 2013). These figures show a tendency to increase as a result of economic growth and a reduction of the price of vehicles being distributed. The number of motorcycles in Brazil increased by 38% annually between 2000 and 2010 while in Colombia and Mexico growth rates has been between 14.7% and 16.4% per year, respectively. On average, cars have increased by about 6% annually in most parts of the global south.

This increase in rates of motorization has consequences on environmental sustainability as a result of externalities such as congestion and air and noise pollution, which stands in contrast with the comparatively low share of demand served by private vehicles. In cities like La Paz, Rio de Janeiro, and Montevideo, less than 20% of daily trips are made by private vehicles. In other cities, such as Bogotá, Belo Horizonte, Porto Alegre, Santiago, Caracas, and Guadalajara, this percentage is still below 30%. These figures contrast with increasing percentages of journeys made by public transport and nonmotorized modes. 45% of people in Maputo, Mozambique, walk as their main mean of transport. In Rio de Janeiro, while in Belo Horizonte, Santiago, León, Guadalajara, and Curitiba, nonmotorized travel represents between 32% and 42% of daily trips. In most cities this is complemented by at least 40% of trips being completed by public transport (Hidalgo and Huizenga, 2013).

Uteng and Lucas (2018) argue that one of the encompassing features of transport planning in developing countries is the central role that automobility infrastructure keeps having, despite the predominance of use by their dwellers of nonmotorized modes. Sagaris and Arora (2017) show that despite more than 70% of trips in Delhi and Santiago are made by public transport, walking, and cycling, key transport policies such as time/space restrictions on rickshaws and a major highway project (la Costanera Norte) keep imposing a system of automobility. Urban street use in developing cities often has a conflicting nature, with a complex pattern of coexistence between pedestrians, vehicles, vendors, and even animals, which also makes interventions more difficult (Dimitriou and Gakenheimer, 2011; Vasconcellos, 2014). In Hanoi, street vending was banned from 63 streets giving privilege to traffic flow over vendors in the urban core.

Pedestrians and users of nonmotorized vehicles account for most of the traffic related deaths in countries with lower uses of motorized vehicles. While in Delhi 43% of road users killed were pedestrians whilst in the Netherlands, Norway, Australia, and USA pedestrians account for less than 18% of the deaths with motorized four wheelers account for at least more than half the casualties. The growth in motorization is accompanied by inequalities in exposures to risks of traffic accidents, air, and noise pollution, as well

as the increased decrease in quality of life, which tends to affect more severely socially vulnerable groups and nonusers of motorized transport. The World Health Organisation recognizes transport-related effects such as exposure to pollution and road accidents as some of the leading global causes of death. These tend to have a much higher effect in global south cities, where most of the population is in a vulnerable position to deal with the aftermath of traffic-related injuries and sickness.

Pojani and Stead (2015) argue that medium-sized cities in the developing world can offer greater potential for more sustainable transformations than megacities. They generally have a smaller ecological footprint, and in principle, their size allows for flexibility in terms of urban expansion, adoption of “green” travel modes, and environmental protection. However, there is the limitation of smaller budgets and technical resources to implement transport programs and projects and probably higher levels of financial, and climatic vulnerability. Also, compared to larger cities in developing countries, generally medium-sized cities are less dense engendering less efficient public transport systems, lower shares of public transport use, and consequently more transport related energy consumption per citizen.

Paradigm Shifts and the Resurgence of Public Transport, Cycling, and Walking

In recent years, investment in public transport infrastructure of high capacity has increased in cities across the global south. An example of such a trend is emerging Bus Rapid Transit (BRT) systems. According to data from BRTData (2020), (104) cities in Africa, Asia, and Latin America have developed BRT systems that add to up to 3590 km in 2020. Something similar has occurred with cycling infrastructure throughout the developing world. By 2011, 327 cities in Latin America had exclusive lanes for bicycles (85% of them in Brazil). Availability of infrastructure by type of transport mode shows an increasing effort by national and local governments to increase supply of public transport and to provide better conditions for nonmotorized travel, although the latter is much more limited.

High densities and mixed uses are necessary for public transport and nonmotorized modes to be financially feasible and practical. To have compact urban forms land-use controls are necessary and consequently these measures have important results in terms of mobility patterns. Measures to manipulate a city’s shape, density, decentralization, and building layout between others can have a substantial effect in city issues such as congestion and pollution (Jenks et al., 2000). In the global south, these characteristics variate highly, with most Asian cities is being highly dense and sub-Saharan Africa cities showing large urban footprints with very low density (Pojani and Stead, 2015).

In China, there has been a renaissance of cycling—in 2005 10 million e-bikes were sold, multiplying by 250 the number sold in 1998. Weinert et al. (2007) attribute such increase to several convergent elements: bike-sharing programs with electric technology that allows for longer distances to be covered, safety regulations, lower e-bike prices, growing incomes, and regulations against gasoline vehicles. In other cities like Bogotá and Sao Paulo, cycle networks have been rapidly expanded, in China motorcycles lanes have been transformed into bicycle lanes (Dimitriou and Gakenheimer, 2011) and Daejeon and Rio de Janeiro have bike sharing systems with fleets of over 200 bikes (Midgley, 2011). This is supported by programs seeking to foster active lifestyles though temporary closures of roads during weekends for walking, cycling, and do physical activity such as Vida Chile, Bogotá’s Sundays Ciclovía, and the more recent cycle days in Kigali, Rwanda.

Institutional Weakness Versus Growing Scope for New Policies

A common trait in global south cities is the absence of analysis to develop a planning process based on specific contexts due primarily to a lack of standardized systems of data collection (Uteng and Lucas, 2018). Pojani and Stead (2017) identify lack of institutional capacity and lack of cross-agency collaboration as main challenges emerging cities face to plan for more sustainable and equitable transport systems. Most developing cities share the need of shaking off accumulated inefficiency in transport practices, institutional weakness, and consolidated power of privately managed public transport with very weak regulation.

Mainstream response to such challenges has entailed structural institutional and operational changes often materialized on high investments in infrastructure. However, weak institutional and physical integration between different sectors of urban and transport planning and operation have led to limited progress in the modernization of urban transport. Financial difficulties in the management, operation, and development of urban transport reflect more structural issues such as poor management, poor institutional coordination, and the lack of comprehensive transport, and land use planning integration. This is compounded by lack of technical training for civil servants and technical staff at local planning offices and a frequent lack of incentives for high-quality professionals to join the public sector.

Lack of effective enforcement of traffic laws and regulations, coupled with weak enforcement institutional capacity and corruption pose another significant challenge for planning, regulation, and decision-making. These are often compounded by complex power relations associated with context-specific cultural and social values. Demand management, road safety, and space management require the resources to enforce the law or otherwise they do not work.

Some of these challenges can be aided by technological developments seeking to strengthen capacity for management and regulation of transport supply, and demand. The most common are traffic signaling, and surveillance, tracking systems, electronic ticketing services and toll collection, bus management systems, and information services (Pojani and Stead, 2017). Implementation of technological aids to improve such conditions depends on the availability of financial resources and requires a change on the predominantly indifferent attitude by local professionals and lack of user trust.

Awareness-raising campaigns as a strategy to reduce environmental impact of mobility patterns in cities are more likely to succeed in global south urban spaces when they are low-cost activities such as car-free days or free vehicle inspection days. Support of charismatic political leaders is important and often even crucial for their reception (Pardo, 2001). Public attitude toward road pricing as a mechanism to reduce car use has been shown to become more positive after the programs have been implemented.

An advantage of command and control measures to manage car use in developing countries is that rationings and banning are interpreted to affect everyone equally, making them politically easier to implement. In Bangkok, a program to restrict all newly registered cars to use exclusively in nonpeak hours was implemented with positive results, while in Guangzhou only locally registered motorcycles can drive in the city. Other cities like Sao Paulo, Bogotá, and Mexico City have imposed temporary restriction based on license plate numbers to reduce congestion and pollution.

Equity, Segregation, and Socioeconomic Vulnerability

Developing cities tend to be spatially and socially segregated with high levels of spatial inequalities. High-income gated communities well-connected to the transport systems stand in stark contrast with low-income informal settlements bypassed in the processes of infrastructure and services provision. Poor neighborhoods also have very poor local supply of employment and other opportunities, which reinforces the negative effects of urban geography in their accessibility and inclusion. In most global south cities, poverty and peripherality are highly correlated, while most informal and poor neighborhoods share a generalized lack of infrastructure and transport supply and investment.

The intersection between poverty, segregated urban forms, and low supply of affordable transport, leads the poor in global south cities to spend a disproportionate share of their income in transport. Carruthers et al. (2005) found that in 2002 in Buenos Aires, the average public transport expenditure to commute to work as a share of income was 31.6% for the bottom income quintile. Transportation expenditures as a share of income were 6.4% and 11.7% for the bottom income quintile in Montevideo, Uruguay and Córdoba, Argentina, respectively. Carruthers et al. (2005) estimate that transportation expenditures as a share of total household expenditures, averaged over the entire population, were 15% in Yaoundé, Cameroon. In African and South-East Asian cities, poor populations walk because they cannot afford public transport fares, trading off affordability for very long walking trips highly exposed to traffic accidents and pollution.

Recent innovative transport strategies have changed some of these narratives in specific cities. Medellín's cable car system has improved accessibility of low-income hillside neighborhoods while increasing access to jobs and influencing social cohesion in the city (Dávila, 2013). Ropeways, air gondolas, or cabled propelled transit systems are fully segregated systems with much limited capacity than other technologies and a considerably lower capital investment. The aerial operation has made this technology a convenient alternative to overcome challenging geographies such as hilly terrains, rivers, harbors or dense, and historic neighborhoods.

Informality and Innovation

An unclear division between formal and informal modes is a common characteristic of governance and operation of transport in global south cities (Uteng and Lucas, 2018). The formal–informal dichotomy in practice is more a continuum of state regulation and unwritten but generalized rules and practices that emerge from established and changing social norms and traditions. Regulatory and service gaps create spaces for private, predominantly unregulated services, that grow without state intervention and sometimes dominate transport markets as in various cities in South Africa.

Informal transport services provide on-demand mobility for people that depend on transit to be mobile while representing an income source for low-skilled workers and the only alternative for areas where there is no formal transit supply (Cervero and Golub, 2007). They involve externalities such as increased congestion, pollution, accidents, and sometimes violence among owners and operators. In Nigeria, informal transport services have grown rapidly since the collapse of formal public transport system that could not cope with growing operation cost encompassed by fare regulation preventing fare increases.

Informal transport solutions have a dominant and pervasive presence in developing countries, but it remains difficult to access information about the lives of those involved in providing informal transport using formal approaches. New approaches to informal transport services are necessary to include these services that are increasingly marginalized in transport planning when cities in the process of policies of modernization in the global south. Similarly, ICT for collaborative paratransit mapping can be a method to close the gap in official planning of a key mobility system and to create a more inclusive transportation planning dialogue.

Across the Global South, the dominant emerging trend amongst paratransit services is perhaps the mushrooming of potentially disruptive digital platforms related to their operation and use. Widespread availability of mobile phones in Asian and Latin American cities has enabled new forms of mobility and changed the organization and operation of informal transport services. Over 150 mobility companies in Africa provide services from journey planning to ride-hailing and cashless fare collection (e.g., Gona in Lagos). In Latin American cities, a fertile ecosystem for start-ups has given rise to either homegrown initiatives, or adaptations of platforms from elsewhere to local conditions. Local and global entrepreneurs have introduced new forms of unregulated services such as “microtransit” and ride-hailing. The operation of these market entrants has been hampered by a lack of public sector regulation and violent acts on drivers by incumbent operators.

Looking Forward: Gaps in Knowledge and Priorities for Research in a Rapidly Changing Environment

The challenge for integration of mainstream approaches to UTP and theories concerning the social dimensions of transport interventions in the global south requires more emphasis on the international and interdisciplinary dialogues on urban development. Global south cities need to overcome the fragmentation in the planning process and develop a framework that can encompass the different dimensions of transport and urban development in all its stages. Social considerations have been limited in practice to the evaluation and monitoring spheres of the planning process, with only some project-specific initiatives to address poverty in some developing cities. Similarly, the influence of shifts in policy priorities and guidelines had a more perceivable effect on the detailed implementation of the UTP process rather than its overall structure.

A recent change of international interest towards poverty alleviation in development has presented an opportunity for transport strategies to play a more active role as part of programs aiming to reduce poverty in urban environments. This has involved the inclusion of new criteria for policy design and evaluation and a debate in developing contexts in relation to the objectives of transport master plans and infrastructure interventions that has not yet been fully explored in the international literature. Moreover, research on approaches to address the specific needs of disadvantaged populations that inform policies in their favor is another gap in current research and practice of transport planning in the global south. The diversity of societal environments, traditions and conventions that underpin gender relations in transport is another relevant area of research as the gendered dimension of transport planning has only been addressed in a handful of works in urban transport research in global south cities. There is a need for additional debates around ways of incorporating a stronger social dimension in theory and practice around urban transport in cities of developing countries.

Other priorities for research in these contexts include the examination of the links between transport and land-use and the added complexities associated with informality in housing, labor and transport in developing cities. Moreover, the contribution of different formal and informal innovations and the role of ICT in urban transport provision, mobility, and accessibility. This includes not only research on the effect of ride-hailing, micromobility, and technological transitions for sustainable transport, but also the many homegrown innovations that entrepreneurs and governments across Sub-Saharan Africa, South-East Asia, and Latin America are producing daily. Finally, the links between transport and health in global south cities, where a large share of the population is suffering from many transport-related causes of death and where the characteristics of society and the built environment may increase vulnerability to health-related risks and concerns are key research priorities.

Such research priorities take place in increasingly changing environments. Recent events in relation to the COVID-19 pandemic have forced researchers and practitioners to rethink the role of transport in society and to adapt its planning and operation. Considering the pace of demographic and economic growth in cities in the global south and their still large gaps in access to basic public services, such challenges are only likely to grow in scale and relevance. A predominantly younger population and expected economic growth annual rates of 4%–5% on average even in sub-Saharan Africa pose challenges that escape the priorities of research and planning in industrialized societies. Issues of urban governance and rapidly changing political environments are likely to pose challenges for new research and planning direction, which need to adapt to transitions to accelerate economic and social development. Despite poverty, inequality, and slow economic structural transformation and violence, global south cities will be at the center of development policy and practice in the following years and transport will continue claiming a key role in achieving more sustainable and inclusive cities, calling for larger focus in these contexts and posing an exciting challenge for researchers and practitioners of transport planning globally.

Glossary

Children's Independent Mobility (CIM) the freedom of a child to make trips or explore their neighborhoods on their own or with friends, without the accompaniment of an adult.

What is Children's Independent Mobility?

Children's independent mobility (commonly referred to as CIM in literature and practice) can be understood in a number of ways. Broadly, CIM is defined as the freedom of a child to make trips or explore their neighborhoods on their own or with friends, without the accompaniment of an adult. In more open terms, it relates to a situation where a child is *allowed* to make a trip or explore without an adult (called a "license"), whether they conduct such trips/activities or not. Typically, CIM is measured and studied in terms of making or having a license to walk/cycle/scoot without adult supervision to and from various destinations such as school, a friend's home, or parks. A child's independence can also be limited to certain conditions such as crossing at controlled intersections, not cycling on roads without segregated bicycle lanes, or not traveling at night; thus traffic-safety condition limits. Finally, with regard to transportation modes, particular focus is placed on a child's use of active travel modes (e.g., walking, scooting, cycling) and public or shared transport (e.g., bus, taxi, rail).

Why is it Necessary to Consider Children's Independent Mobility (CIM) in Planning?

CIM has a wide range of positive impacts for children (Waygood et al., 2017). These impacts can be organized with respect to their domain of well-being (Fig. 1). For children, CIM may affect their physical, social, psychological, cognitive, and economic well-being.

Physical well-being relates to benefits or harms that relate to the physical state of the child such as physical activity gained through active travel or exposure to outdoor air. Social well-being impacts relate to the social state of the child and include impacts such as the likelihood of a child meeting with friends or the child's community connections. Psychological well-being relates to the child's psychological state and relates to impacts such as travel satisfaction, life satisfaction, and happiness. Cognitive well-being is a sub-category of psychological well-being and generally relates to learning (formally or informally). Its impacts include increasing knowledge of one's living environment, being alert/awake and ready to learn. Finally, economic well-being relates to the economic state of the child and includes impacts such as the cost of travel or parental time use (as transport theory generally aims to reduce travel time of adults so that they can do productive work). Many of the benefits gained relate to active travel (e.g., physical activity, social interactions, satisfaction, being alert, low financial cost), though benefits also relate to public transportation options as these allow a greater range and thus increase the possible destinations a child could reach independently.

Children's independent mobility also relates to many current transport issues such as climate change emissions and energy use, road safety, transport costs, and congestion. An independently mobile child would use active travel modes (such as walking or cycling) and public transport for reaching various locations, and as a result, emissions are generally lower. Active travel modes do not create significant danger to others, and fatalities when traveling by public transport are extremely low. A child who is walking, bicycling, or scooting is a more vulnerable road user compared to those in motor vehicles, however, motor vehicle travel is

Figure 1 Conceptualization of how CIM relates to child well-being with examples.

intrinsically dangerous due to its speed for both the child in the vehicle and children outside the vehicle. In terms of transport costs, travel by active and public modes are less expensive than travel by car though people may not perceive it as such. Congestion is a problem of space, and public transport is the most efficient use of space followed by active modes. Finally, children who travel independently acquire the skills and familiarity with such modes through socialization and practice, and are thus more capable and likely to use the modes as adults.

Within planning, children can be considered as a marginalized group, as their inclusion and needs are not overtly taken into account. A lack of consideration to CIM has likely contributed to the modern problems of high chauffeuring burden and schools being located near heavy traffic. In contrast, planning for CIM creates travel contexts where most road users are able to travel safely and independently, including adults who do not use private motor vehicles (whether by choice or not). It also ties into the United Nation's Convention on the Rights of the Child ([United-Nations, 1989](#)), which states at various points that the child's survival, development, and well-being must be ensured. As CIM is positively linked to many such measures, its inclusion in planning is essential to protect the rights of children and develop cities for all.

What Influences Children's Independent Mobility (CIM)?

The influences on CIM can be best understood by examining a household's transportation decision-making process and the social and environmental contexts within which these decisions are made. A child's mobility outcome is the result of decisions around three key components, namely: the destination, the accompaniment (i.e., whether a child is traveling alone or with someone else, which could be other children or adults), and the transportation option or mode of travel. Adult household members and children negotiate these outcomes based on: (1) the importance of an activity (obligatory versus discretionary), (2) a child's perceived ability to independently travel and explore, and sometimes (3) the caregivers' availability and ability to facilitate a trip. Each household will make these decisions within different contexts, and these contexts will influence CIM outcomes. After several repeated occurrences, a transportation outcome may become habitual, unless any change in the social-ecological environment warrants a reassessment ([Mitra and Manaugh, 2019](#)).

A limited but emerging literature has examined various aspects of the social, physical, and policy environments that may influence a child's transportation outcome and consequently, CIM. These potential influences are summarized in [Fig. 2](#), using a social-ecological model framework. A child's physical and cognitive maturity as well as self-efficacy (i.e., their belief in themselves to conduct the trip without an adult) are important indicators of their license to independently travel and explore. A household's social and economic conditions and available transportation options will also influence travel behavior outcomes. Though in some countries girls' mobility are found to be more restricted, the relationship between gender and CIM are not conclusive. Age is often used as a proxy for a child's physical, cognitive and social development and experience, and it is generally expected that CIM increase with age. However, at what age CIM is allowed is found to vary by culture and context. Children in Japan and Finland are found to

Figure 2 A social-ecological model of children's independent mobility and transportation outcomes. Source: Modified from Mitra and Manaugh (2019).

have considerable CIM at age 7, whereas in other countries such as the United Kingdom and the United States, CIM is not common until children are 10 or even older.

The built- and social-environment of a neighborhood may also influence a child's mobility outcomes by forming social expectations, travel-related attitudes, and perceptions of "walkable/bikeable" distance and safety. More broadly, the natural environment (e.g., topography, climatic conditions) and policy context (e.g., school selection and bussing policy) may also influence CIM, be it enabling or restricting CIM. Finally, all these potential influences may vary depending on the context within which a household is making their transportation decisions.

What is Urban Planning's role in CIM

Emerging evidence emphasizes the role of urban planning policy and practice on a child's mobility, and in particular, their independent mobility. In nearly all studies on CIM, distance between locations was identified as a key barrier to CIM, as most children would make these independent or unsupervised trips using active modes of travel, including walking and bicycling. As such, accessibility to both residential (e.g., a friend's house) and non-residential (e.g., school, playground) destinations is a key element of the "planned" built environment, that may enable or restrict CIM in urban, suburban and rural communities. Communities with a higher population density can support a greater diversity of local opportunities such as schools, playgrounds, and sport/leisure and cultural activities within a short distance. However, higher density development, sometimes called vertical neighborhoods, generally reduces residential space, availability of public spaces where children can meet and play, and also may result in crowded streets that are considered unsafe for a child. Partly as a result, families with children across North America and Europe have moved away from urban downtown locations which are actually accessible, diverse and typically enable CIM, to more suburban neighborhoods with larger residential space but limited opportunities to walk/cycle for a child. This reduction in CIM and reduced density of such developments can lead to lower levels of social and physical play, and higher traffic speeds along with vehicle dependence keep traffic danger high. Recognizing the apparent "absence" of children from downtown neighborhoods, some cities are investing in making their urban neighborhoods child-friendly. While more common in Europe (including Stockholm and Helsinki), North American cities such as Vancouver and Toronto have also developed guidelines to make families with children more "welcome" in vertical neighborhoods. Ensuring a balance between spaciousness, proximity, land use diversity, and traffic safety remains one of the key challenges in such efforts.

There are several critical challenges to address when planning communities for children. Parents obviously play a crucial role in CIM. Two key factors that emerge in studies on CIM are fear of traffic (traffic danger) and fear of strangers (personal security). Traffic danger appears to be the larger of the two concerns, and both are often found to increase with distance from destinations. Contemporary parenting culture emphasizes constant supervision of children and this approach propels some of these concerns. For example, some studies have shown that walking to school has declined over time, despite no changes in average travel distance to

school. In other words, the perception of what is considered a walkable and safe distance might have changed over the past decades across North America and Europe.

Another role that parents play pertains to attitudes and skills relating to CIM modes, including walking and bicycling. If a parent expects that a child will be able to travel independently, they will generally facilitate this by practicing with the child and helping them develop the necessary skills; also known as socializing. They may also choose a residential location that will be conducive to such travel (known as the residential self-selection). What is encouraging is that parental and children's attitudes can potentially be altered by systematic programming focusing on skills and experiences. Examples of such programming include walking school buses, bicycle training at schools, and doing class excursions by public transport. National walking school bus programs have existed in Japan for decades and have now become popular in other countries in the global north, though most implemented programs in western countries are ad-hoc and not coordinated across schools or school boards. Examples for safe bicycle training include Austria's *Verkehrsgarten* where children can train and develop their bicycle skills in a traffic-free zone. In the Netherlands, where the largest mode share for trips to elementary school is by bicycle, theory on general traffic rules use is given at school through programs such as Streetwise, and bicycle exams occur on the street.

With regard to the planning of the built environment, street design can facilitate or limit vehicular traffic, and as such will increase or limit traffic danger. For example, wider streets facilitate higher vehicular flow and speed and are thought to improve the safety of vehicle occupants, but they decrease the safety of other road network users. Higher speed traffic (above 30 km/h) increases the likelihood of a fatal collision when a child is involved in such an event. Restraining vehicle speeds through street design can increase CIM by not only reducing collision severity, but also by reducing the road crossing distance. Traffic engineering at controlled intersections, such as signal length (i.e., time allocated to pedestrians to cross a street during a green light) is also important. Previous standards for crossing times were roughly 1.2 m/s, based on physically capable adults, but a recommended speed to include most residents including children is 0.8 m/s (NACTO, 2013). With regard to street layouts, curvilinear roads, typical of many suburban developments, were originally designed to restrict vehicle movement by narrow lane width, reducing sight lines, and circuitous roads. However, traffic-engineering standards resulted in large vehicle lanes and long sight lines, which do not restrict vehicle movement. Circuitous roads limit through traffic, but without more direct active travel paths, result in longer walking/cycling distances between destinations even when the direct path distance may be short. Grid-patterns are easy to understand and thus navigate, but their scale will affect CIM.

In recognition of the importance of street safety, urban planners, traffic engineers and community organizations have adopted several approaches that may improve walking/bicycling to common destinations such as elementary schools, and by doing that, enable CIM. The most common approach is limiting vehicle speeds in school zones (often to 30 km/h). Programs such as Safe Routes to School (SR2S) in the US and School Travel Planning (STP) in Canada aim to improve the likelihood of active travel through education and infrastructure changes (National Center for Safe Routes to School, 2010). School travel corridors are another means of promoting active travel and CIM by limiting speeds on such routes and making infrastructure changes such as those mentioned earlier. Limiting through traffic to only local residents during school commute hours can reduce traffic danger in a more zonal approach (as opposed to just certain routes). This is applied in Japan where generally no through traffic is allowed within 500 m of elementary schools during school commute times.

The other components of built-environment planning—the density and diversity of land use—are also important for CIM. Population density by itself can increase the likelihood of desirable destinations whether that be playmates or a music teacher living within a reasonable CIM distance. However, without a mix in land uses, the diversity of possible destinations, and thus activities, is limited. CIM is found to be higher in areas with a greater diversity of land uses as they facilitate independent trips to schools, parks, libraries, recreation, shops, health services, and so on, which would all be located within close proximity of a child's home. Higher population density may also stimulate CIM as local play destinations are more likely to have other children present with whom the child can play, and thus provide the critical mass for group play.

Current and Future Considerations

Children's independent mobility, and children's mobility in general, has attracted much attention from public health in recent years. Transportation has long been known to be dangerous due to collisions, but more and more evidence demonstrates a wide range of negative impacts from sedentary lifestyles, emissions and noise. Collisions and sedentary lifestyles are perhaps more commonly discussed as collisions can result in fatalities and debilitating injuries, while sedentary lifestyles have been shown to relate to various physical health problems relating to body weight and cardio-vascular health. Exposure to vehicular emissions are increasingly linked to issues such as children's asthma, cancer, and even attention deficit disorder. Noise and vibrations are linked to sleep problems and cognitive ability (Waygood et al., 2017).

Over the past 2 decades, the Swedish approach to road safety, named "Vision Zero" has increasingly been adopted worldwide (Kristianssen et al., 2018; Ludvigsson et al., 2017). This approach differs from previous paradigms where many collisions were blamed on user error. Vision Zero takes the approach that the system must work to design out fatalities and serious injuries resulting from human error. As such, many residential streets are being redesigned/regulated to accommodate all users including children by restricting vehicle speed, and where speeds are above 30 km/h, by having protected infrastructure. Protected infrastructure for vulnerable users must not be seen as a cost of active travel, but a cost of high mobility as it is the source of the danger and must pay for its externalities.

As the new mobility options such as shared vehicles and autonomous vehicles continue to emerge, the role they will play in children's travel and their independent mobility is yet to be seen. For shared vehicles such as bicycles, the sizes are often too large for children under 12 and (bi-)laws may restrict their use, especially in the case of electric bicycles. Electric scooters also generally have similar restrictions in terms of age, and it is not uncommon for both electric vehicles to require helmets, which limits spontaneous/unplanned use. The use of such modes by children is not well studied, but anecdotal evidence suggests that teenagers do use them, and they do provide additional mobility options that could decrease reliance on high-cost personal motor vehicles.

With respect to autonomous vehicles, very limited research has been conducted on their potential impact on children. Proponents suggest that such vehicles would improve mobility for those without access to private motor vehicles, including children. However, in the case of children, parents would need to be confident with the safety of such systems and would likely need to authorize their dependents to use them. If safety standards are felt to be sufficient and costs were reasonable, it is not unforeseeable that families would use them, as it would facilitate children's travel to diverse destinations at greater distance without the time burden. If, like other common-use technologies, unlimited use service packages are created, this may lead to even further reductions in active travel, though it may be deemed independent. How society would react to such a vehicle killing a child is yet to be seen as well. People may accept human error, but it is not clear whether they would accept programming or equipment error on the part of autonomous vehicles. The overall impact is very difficult to anticipate, but it may result in a Wall-E type mobility future where sedentary lifestyles are completely facilitated.

On a more human side, the inclusion of children in planning is increasing. Although not common, guidance and examples are available, and outcomes support the argument that children's perspective differs from adults' and their inclusion in the planning process results in more inclusive design, making a more equitable system. Transportation planning is perhaps an area where the inclusion of children's needs is most limited and their voices, either directly or through advocates, is rarely taken into account. The basis of traditional transportation planning is value of time, which relates to a person's workforce contribution, which does not exist (for the most part) for children. The approach that planning for adults, and thus parents, includes planning for children raises questions of inter-generational equity and has perhaps led to the current situation where more and more children are dependent on adults for their travel as their needs are not properly considered.

A Need for Change in Planning Perspectives

Approaches to transportation planning are shifting from facilitating high-speed, high-flow traffic to enabling travel by all people (i.e., "basic mobility") and limiting negative health and economic externalities relating to human mobility. Public health considerations will increasingly help support the arguments for better planning for children's independent mobility. However, CIM is a multifaceted issue where addressing only one part of the problem will not likely result in significant changes. Improved infrastructure may make it possible for children to travel by active or public transportation options, but if their destinations are not accessible by those modes (due to distance or routes), only small gains may be achieved. As well, the advantages and disadvantages of separated versus (low speed) shared road spaces are not clear. If social norms related to children's travel do not shift away from an expectation of constant adult accompaniment for all daily trips, then improving safety and destination diversity may only produce small shifts in travel behavior. As such, urban planners and traffic engineers must look to build (either new or retrofit) infrastructure that accommodates safe active travel for all ages and skill levels, diversify destination options through mixed land use and supportive population densities, while also actively involving parents so that their habits and social norms shift over time. As such, improving children's independent mobility requires not only creative thinking in traffic and urban design, but also the adoption of inter-disciplinary approaches involving insights from the fields of sociology, psychology, and marketing. Law enforcement also plays a role, as it can help limit dangerous road user behavior. Ideally, street design would guide people to safe behavior, but this is not always possible. However, law enforcement may only occur at certain times if it is reliant on police presence. The role of automated enforcement, and its acceptance, is not well studied in the context of children's travel.

Although much has been learned about children's independent mobility or CIM in short, more remains to be explored. An exhaustive list is not possible here, but several avenues of investigation are proposed. For example, with regard to the benefits of CIM, while an emerging literature has focused on the relationship between CIM and physical health, the other domains of well-being are understudied. Our understanding of transportation infrastructure designs that are child-friendly is in its infancy, and the potential CIM gains as a result of such infrastructure is largely unknown. Finally, the development of planning tools to better facilitate the inclusion of children's independent mobility in our communities is badly needed. To address these issues, some have recommended including children in the transport planning process, however, in the current practice that has only been marginally addressed.

Biographies

E. Owen D. Waygood graduated in 2009 with a PhD in Civil Engineering from Kyoto University (Kyoto, Japan). After a position as a research associate and then research fellow at the Centre for Transport and Society at the University of the West of England (Bristol, United Kingdom), he held a position of Assistant and then Associate Professor of Transport Planning at Laval University (Quebec, Canada). In 2018, he was recruited by Polytechnique Montréal as an Associate Professor of Transport Engineering. He has published research on children's transport, physical activity, and social connections, sustainable transport, and transport behavior change. He has been a co-guest editor for special issues on transport and child wellbeing, and transport and wellbeing published with the journal *Travel Behaviour and Society*. He was the lead editor for the book, *Transport and Children's Wellbeing*, published in 2019. He conducts research on sustainable transport modes and how to increase their use.

Raktim Mitra is an Associate Professor of Urban and Regional Planning at Ryerson University (Toronto, Canada), where his research focuses on the intersection between the neighborhood built environment and transport behavior, and the impact on health outcomes such as physical activity and the quality of life. Mitra is the co-director of TransForm research laboratory of transport and land use planning at Ryerson University, co-chair of a paper review subcommittee (Bicycle Transportation) at the Transportation Research Board. His previous contributions include co-editing a special issue on the topic of transport and land use in childhood for the *Journal of Transport and Land Use*, and he is also the co-editor of the recently published book *Transport and Children's Wellbeing*.

Introduction

It has been slowly revealed in planning and transport disciplines that far from acting in a singular public interest, professionals tend to deliver policies in line with their own experience. The modernist, universalizing principles that dominated thinking and policy in such disciplines in the second half of the 20th century in actuality proved to be highly damaging to many citizens' health and quality of life and resulted in poor outcomes for nature and the biosphere. The built reality of modernist transport planning also favored individualized transportation options. The subsequent dominance of cars in urban and rural landscapes was closely linked with ideas of personal freedom, which in planning practice meant a freedom to drive one's own car. The policy aim, not always explicitly stated, was to keep motor vehicle traffic moving at as high speed as was practicable.

The consumption of car use embodied a set of economic, emotional, cultural and esthetic responses described in Urry's idea of a "system of automobility" (Urry 2004). The rise to dominance of such a system is now revealed as not the politically neutral, "technical," response it might have been thought of at the time. Rather, automobility is a sustained political project underpinned by lobbying and vested interests and through the often unconscious bias inherent in practices enacted by professionals. Such practices frequently favor certain societal groups such as the able-bodied, men, professional classes, and majority ethnic populations. They also prioritize the human species over others and wider ecological conditions. In short transport policy in most nations and cities is socially and environmentally unjust. Flows of transport finance disproportionately benefit the already hypermobile: big infrastructure projects unduly favor car owners or those able to afford expensive rail fares and multiple flights a year. Lower income residents are typically disproportionately reliant on buses and on walking where public spending is inadequate and the quality of service is often poor (Lucas, 2004). Such residents are also disproportionately more likely to live in environments polluted by the highly mobile.

Transport disadvantage is not just related to poverty and low income. Disadvantage has a sociological dimension closely related to age, gender, and ethnicity. In terms of age, the young and the old tend to be disproportionately affected by the system of automobility. As countries around the world find themselves with increasingly ageing populations there are varying opinions on the policies that promote human flourishing among older people. While car use is often central to many older citizens, public transport, and good walking infrastructure is of equal if not greater importance, especially to those with fewer financial resources. Similarly children have long been seen as victims of policies designed to encourage the free flow of car traffic. A decline in child health, a rise in obesity, and asthma, alongside the psychological damage caused by the limiting of childhood freedoms known to previous generations, have all been highlighted in research dating back to the early 1970s (Hillman et al., 1990). As such, universal design principles that better acknowledge these systemic biases need to drive mainstream policy debate.

Finally, while there has been considerable advancement in ecological legislation around the globe in past decades, much contemporary policy is still anthropocentric. Policy and investment strategies are rarely strongly shaped by the highly damaging impacts to nonhuman species and local and global ecological conditions that arise from human hypermobility, air and car travel in particular.

Facilitating Infrastructure Supply Through Predict and Provide

Strategic policy directions, and the methods, education systems and practices that support such directions, tend to cohere into dominant paradigms or assemblages of practices, habits, theories, behaviors and artifacts. Such systems of meaning then rarely change dramatically: dominant paradigms emerge and become hard to displace. The 20th century saw the emergence and embedding of "predict and provide" as an overarching paradigm for transport planning, underpinned by neo-classical, "orthodox" thinking derived principally from the disciplines of economics and engineering (Vigar, 2002). Given the pressure to accommodate rises in car use in most nations, either among elites or mass populations, such a paradigm resulted in the provision of more road

space for private vehicles, and limited attention to public transport, cycling and walking. A neglect of alternatives to the private car was evident even while such modes were popular and thus this form of planning became a self-fulfilling prophecy as road space grew and other modes were made less attractive as they became starved of investment.

Historically, the politics of such predict and provide thinking was rarely considered by the planners, politicians and engineers implementing it. Catering for forecast increases in car ownership and use was simply good government and the political debate was typically at what speed and cost could road space be delivered to meet the projected growth. Similarly decline in public transport and cycle usage was predicted and systems were shrunk and not catered for, creating a self-fulfilling policy prophecy.

Slowly the politics of such choices was often revealed, at first through citizens mobilizing to protect urban spaces and neighborhoods from urban motorway construction in major cities like New York and London. Then, in many nations, the impact of interurban motorway building received sustained attention from those protecting the place qualities and ecology of rural areas. In part to bypass accusations of NIMBYism, such protests challenges the forecasting assumptions on which predict and provide was based. Latterly issues of climate change and the impacts on nonhuman species of facilitating private mobility became significant features in transport research and advocacy, if not always influential considerations in transport policy and decision-making.

Criticism of predict and provide methodologies often centered on the narrowness of techniques derived from economics and engineering disciplines. However, when it comes to the politics surrounding large infrastructure projects, as Bent Flyvbjerg's research has consistently shown, even narrow means-end rationality centered on economic cost-benefit tends to be ignored or willfully manipulated (Flyvbjerg, 2003). Here politics takes on its rawest form with decisions made with little regard to the outcomes of evaluation methods. To some extent this is a fair reflection as large-scale projects will have unforeseen and unknowable consequences given the time it takes to implement them and the many exogenous shocks to economic and other systems during that period. But the reality is that such initiatives are often the pet schemes promised to electorates and/ or those that are seen to carry large amounts of political capital, rather than projects that will improve the city for the citizens most in need or for ecological conditions.

At the other end of the spectrum much policy and decision-making is often carried on in a "path dependent" fashion with little political oversight. Here conservative transport policy communities tend to deliver largely what they delivered before and budgets tend to be tweaked rather than fundamentally reviewed. This has been highly problematic given the "new" policy goals of climate change, air quality and public health which demand very different policies to those that came before.

Thus, the "predict and provide" approach has proved remarkably resilient despite such challenges, and beyond a few alternatives it lives on in many nations and places well into the 21st century. However, much research suggests otherwise, its intuitive ideas of catering for growth and dealing with congestion by increasing infrastructure supply still resonates with many politicians and citizens in particular.

Sustainable Mobility and Global Exemplars

While the research evidence is clear that urban car use must be managed in some ways, it has proved hard to challenge the intuitive arguments underpinning predict and provide. There are also powerful vested interests perpetuating the system of automobility, whether capitalist - the spending on car advertising globally amounted to some US\$50bn^a in 2018 for example - or "hypermobile" affluent citizens who lobby to protect their lifestyles built around private vehicle use. We should also note the considerable lobbying effort worldwide directed at autonomous vehicle development which could go some ways to softening some of automobility's externalities, but in all likelihood is not going to tackle many of the social and environmental impacts of vehicle usage and could make some conditions worse (Pangbourne et al., 2020).

The most coherent paradigm mobilized to displace "predict and provide" is David Banister's sustainable mobility paradigm (SMP) which foregrounds environmental concerns but also acknowledges the deep inequities present in actually existing transport systems throughout most of the world (Banister, 2005). That said, some commentators emphasize the SMP's dependence on existing, off the shelf, solutions such as pedestrianization and argue that while these do have benefits, they rarely tackle the deep inequities present in mobility in the wider city (Kębłowski et al., 2018). Experiments in free public transport is one example of an alternative that might provoke more radical change and tackle wider injustices.

While a few such experiments are taking root across the globe, many towns and cities are struggling to implement planning and transport strategies that deliver more sustainable mobility practices. The embeddedness of the car in everyday life has made taking back road space for walking, cycling, and public transport prioritization difficult beyond central area pedestrianisations. Urry's "System of Automobility" is deeply embedded in many nations and aspired to, consciously or not, in others, supported by a huge capitalist infrastructure of advertising and government lobbying and in many nations hardwired into the thought worlds and practices of many professionals.

Where more sustainable mobility policies are arising, they are built not just on the long-standing debates highlighted above, but also on increasing evidence about the positive impacts of place making approaches from exemplar cities that have prioritized high-quality public spaces across the city not just downtown. These spaces can then be connected by high quality, safe walking, and cycle networks and affordable, efficient public transport. Urban development schemes in such exemplar cities, Bogota and Copenhagen for example, are often implemented with an emphasis on design quality, where a strong and confident city government has been a

^a <https://www.zenithmedia.com/wp-content/uploads/2019/03/Automotive-adspend-forecasts-2019-executive-summary.pdf>

constant feature, and sometimes with the consistent support of ruling governance regimes irrespective of the electoral cycle (e.g., Emanuel, 2019). In such places attempts to shape travel behavior go beyond central areas to retrofit existing neighborhoods to prioritize active travel and encourage people to see the street as public space and not a canal for car traffic. Critically, these packages of measures have demonstrated considerable economic benefits with many such cities being among the most successful on their respective continents.

Governance for Sustainable Mobility Policy

While economic issues are no doubt important, transport policy is often seen purely through the lens of its role in facilitating economic growth. Slowly the significance of transport policy in meeting climate and ecological targets as well as shaping the health of citizens, has begun to emerge. There is no doubt that research is playing an important role here, from increasing evidence of the impact of for example automobile traffic on human lung function in cities through exhaust emissions and tyre and braking systems, to transport's role in the climate emergency. Governance systems have generally been slow to adapt to such evidence and often favor light green, technocratic, approaches to deal with them, such as the promotion of electric vehicles.

But change can be rapid. The presence of a powerful city mayor can be one way that cities, such as London and New York, have been able to reasonably rapidly implement more sustainable policies, often where new mayors have been elected partly on the basis of changing the transport status quo. The key in reshaping policy direction in both these cities was to act quickly despite the opposition, to demonstrate that the city did not become grid locked when demand management measures and restrictions on car use in particular were implemented. Such measures have been most successful when complemented by affordable supply improvements, to show that the city worked better for most people than it did before (Sorenson et al., 2014).

An alternative to powerful mayoral action lies in more participative methods whereby citizens, through referenda or citizen juries or other deliberative methods, opt for such policies. There is contrasting evidence of the willingness of citizens to embrace elements of sustainable mobility where they see much of this agenda as a restriction on their current mobility practices centered on the use of private cars. But in neighborhoods where car traffic in particular might be dominant, citizens are more likely to opt for redesigned streets and public spaces than when imposed by "expert" planners and engineers. And this can be a "way-in" to lobbying for such policies at more strategic levels.

Such processes of co-design can help citizens imagine transitions to more sustainable mobility and more liveable urban futures. To realize such imaginings, creativity is needed at the center of any approach—a vision of what might be—as many of the global sustainable transport exemplars have emphasized. Design processes become research processes allowing for uncertainty in ways that traditional transport methods falsely seek to eliminate. Storytelling, making and enacting are vital to such processes using physical artifacts, sketches, 3D models, and virtual objects, all as provocations within the process as well as visions of the future. The temporary urbanism movement has shown how demonstrating a new vision through the use of traffic cones, straw bales and paint before implementing an expensive scheme is a powerful way of getting buy-in from businesses and citizens. Such open-ended and iterative approaches allow citizens to talk back to designs, informing and refining the proposals, standing in contrast to traditional linear processes of transport modeling, land-use planning, and for that matter traditional consultation. Temporary interventions are increasingly powerful tools to demonstrate that change is possible and that initial reservations among a majority of citizens may be misplaced.

The materiality of many such interventions can help dismantle established power relations, requiring engineers and planners to let go of some of their traditional forms of expertise. One role of engineers and planners in such strongly participatory process is to provide their knowledge of models and their limitations, of antecedent and precedent in terms of what might be possible, using the global exemplars we all know about and the research evidence about the links between transport behavior and economic growth, environmental impact, and social justice. But this is just one package of knowledge in a widely distributed urban intelligence. Such processes are not easy, but if cities are to "Copenhagenize," putting sustainability and place making at the center of their city visions, relying solely on traditional transport and urban planning approaches is unlikely to work (Colville-Andersen, 2018). Transitioning to a radically different mobility system requires demonstrations of what might be possible, both at the city scale and in neighborhoods, in the context of local circumstances and priorities, and with citizen representatives actively engaged in some form or another.

These approaches might be incremental, as in Copenhagen where car parks in the city center were restricted and closed slowly over time, while the city authorities went about building bike lanes and improving the pedestrian environment. Or it might be done at speed such as in Bogota in the late 1990s and early 2000s, driven by a mayor with radical ideas. Fundamentally both cities succeeded because there was a strong, well-articulated vision and desire for a better city. The willingness to experiment, to do things differently, was also important, as was political support for the project regardless of electoral or economic cycle. While there is a lot of talk of smart cities and the power of new technology, we should not forget that decades of top-down modernist planning prioritizing the car have left us in desperate need of ordinary things: benches, crossings, well-kept pavements, car free areas and cycle paths all greatly helping connect, strengthen and enliven communities. The global exemplars emphasize these needs strongly.

Conclusions

Buckminster Fuller asserted that change did not come from fighting the existing rationality but by building alternatives that render the existing obsolete. Movements such as Extinction Rebellion and lots of urban social movements are trying to do this and we see

some of this evident in the transport planning approaches of exemplar cities where demonstrating alternatives has been a key feature in facilitating more strategic change.

Some critical voices suggest that measures such as bike lanes and pedestrianization are the form of environmental gentrification, forcing the priorities of hipsters on less vocal majorities. But such experimentation can be grounded in broadly-based participatory democratic forms—as in the case of streets renaissance in New York and in Bogota—underpinned by local leadership capable of providing the framework within which such experimentation can emerge.

Many will also point to the rise of urban neoliberalism and the dominance of narrow forms of market rationality and of vested interests standing in the way of more equitable and just transport policy and spending. Considerable money is disbursed, and many are employed, in the transport realm often in a very path dependent way with little preconception of how budgets could be deployed differently. Indeed, considerable resources are wasted each year on defending policies and plans that have not been developed adequately with the participation of interested citizens and which lead to a great deal of protest. But global exemplar cities such as New York show how all sides of the political spectrum can get behind reclaiming streets from private motor vehicles and as Jane Jacobs noted in that City over 60 years ago, the urban street can be the most fundamental part of city life for citizens and we might do well to adopt this as the overarching principle for future urban transport planning.

Introduction

Technology enabled data (as a subset of the broader big data landscape), have been highlighted as a strategic priority in policy agendas and national/international funding (EC, 2019; Lalawat, 2018; NITRD, 2016; NSFC, 2018). The UK Department for Transport has identified data and digital technologies “as a key enabler for innovation and a foundation for enabling the future of mobility”, whilst “improved transport data will allow the creation of innovative business models which have the potential to change the way people and goods are moved” (DfT, 2019). More broadly, the “rigorous analysis of high-quality data can enable citizens to hold governments to account, drive improvements in public services by informing choice, and feed innovation and growth across sectors by providing a robust evidence base for policymaking and practice” (ESRC, 2016). This article focuses on the potential of technology enabled data (hereafter referred to as “New and Emerging Data Forms” (NEDF)) considering the policy needs of the transport sector and sustainable mobility specifically.

NEDF include, but are not limited to (ESRC, 2016; OECD, 2013):

- *Internet data*, derived from social media and other web-enabled interactions (including data gathered by connected people and devices, e.g., mobile devices, sensors, wearable technology, Internet of Things),

- *Tracking data*, monitoring the movement of people and objects (including GPS/geolocation data, traffic and other transport sensor data, CCTV),
- *Satellite and aerial imagery* (e.g., Google Earth, Landsat, infrared, radar mapping)

Data need for sustainable transport policy may differ in one important respect from many other sectors. The efficient and sustainable operation of the transport sector and its ability to meet the mobility needs of society relies on understanding the unconstrained demand, dynamic interdependencies, physical interactions, and variety of *externalities* generated by multiple individual mobility choices. In summary, as individuals choose to travel and enter the transport system by whatever mode, their presence in the system impacts on others, on the functioning of the system and on the environment.

From an alternative perspective, many of the data need for mobility are clearly similar to those of other sectors (health, education, energy, and more), including the needs for privacy, data security, data quality, timeliness, and governance structures. The transport sector equally has a need for improved understanding of the value proposition (business model) for a range of actors in the sector, but chiefly, the value for members of the public who may generate the data.

A set of additional requirements for mobility data has been apparent despite a wealth of established data forms in the sector (large scale census, household surveys, embedded fixed-base sensors and more). The emergence of NEDF as a result of recent technology advances and utilized solely or in conjunction with more established data forms raises further questions about their contribution to the data need for sustainable mobility and policy makers.

New Offerings for Policy Makers

Transport Network Modeling

The modeling of individual movements, the state of the transport network and characteristics such as mode share have played a long-term and key role in the development of tactical and strategic transport policy. Highly refined models have been developed using traditional data sources, however with known issues due to the input data available. NEDFs have the potential to replace or enhance traditional transport data in creating high quality origin-destination matrices for transport modeling (Cuauhtemoc et al., 2017). Traditional transport data can be expensive to collect and may only offer a crosssection of travel patterns. In comparison, new forms of data are often collected automatically, digitally, at a high level of temporal granularity, and may be more comprehensive at a lower cost. More variable and customized outputs and more realistic representations of local transport supply and demand offer new opportunities to policy-makers as they appraise projects.

Data generated by mobile phone networks (call data records (CDRs) and network connections) have received particular attention, though other forms of technology enabled data, for example, from smartcards, social media, and GPS within mobile apps or vehicles, also enable model development (Harrison et al., 2020). Examples include detailed and comprehensive spatial data on cycling and walking patterns from Strava Metro data, tracking of passengers through stations through WiFi/Bluetooth Connections and testing short-term forecasting methodologies.

Other opportunities for established transport network modeling include:

- With repurposed data, the sample size may be considerably larger than could be the case if primary data were generated. It may also be possible to link the data of multiple travelers (e.g., friends traveling in groups).
- Many new data are dynamic and often available in real time. This makes it easier to update models, calibrate the models in real-time (or close to real-time), and provide timely analyses to inform current policy decisions.
- The continuous generation of data enables panel data to be constructed (i.e., long series of observations of the same individual). This can support analyses of within-individual changes and reduce the risk of bias inherent in cross-sectional analyses.
- Passively generated data may be more reliable than traditional sources such as surveys, which may exhibit response (or nonresponse) bias, arising from fatigue for instance.
- The combination (or linkage) of related available datasets to new forms of mobility data may help to overcome the lack of specific attributes needed for effective modeling and decision-making.

Emerging Modeling and Analysis Methods

New modeling and analysis methods are being adopted by the transport sector to harness new data. Research using NEDF, sometimes in combination with, or in comparison to, other data sources, has expanded from building and validating transport models to wider “smart cities” applications. These assess the intensity of activities over time and location, including during irregular events. Simulation models can test the impacts of policy options on outputs other than network efficiency (e.g., environmental impact), such as agent-based modeling or system dynamics modeling, and choice modeling to assess preferences of individuals. An approach gaining popularity for the analysis of large-scale databases in the transport sector is machine learning, part of the more general field of artificial intelligence. This comprises techniques able to uncover patterns inside a dataset (training set) which then use that knowledge to predict, or to recognize patterns, inside new datasets. Several statistical techniques and algorithms developed in computer science have been implemented for combining “redundant” sources of information, such as Bayesian inference, artificial neural networks, fuzzy logic and Kalman filters. Examples of such type of data sources are the traditional inductive loop detectors and the emerging sensor data, measuring the traffic flows in a road network.

Cross-Sectoral Modeling

There is an increasing need amongst policy makers at all levels to develop cross-sectoral policies, which consider and satisfy objectives from multiple spheres, including public health, environment, land use, and social equity. Transport traverses all these sectors so technology enabled data for sustainable transport policy has significant influence on the appraisal and implementation of cross-sectoral aims. Existing practices from areas such as healthcare and the finance industry may provide some guidance for the treatment of sensitive data, particularly as location identifiers are now considered “personal data” under General Data Protection Regulation (GDPR) guidance. From the vantage of healthcare data protection and public trust are key concerns, whereas research and emerging practices in financial technology may also provide valuable insights into the regulation and use of data. Early collaborative engagement of specialists/policy makers in these areas, each with their own objectives can lead to a true cross-sector model rather than an “adapted” single sector model. Furthermore, there is also the potential to detect previously unconsidered mutual benefits or trade-offs using the new forms of data.

Positively Disrupting Travel Choice and Behavior

There is a substantial body of work dedicated towards using NEDF to analyze and better understand the route and mode choice of travelers, which can lead to more effective policy decisions. This includes the use of GPS data to better understand route choice, CCTV and Wi-Fi data to map crowds and Bluetooth data to classify types of road user. Research has also focused on how to use the information to subsequently influence planning and policy decisions. An example of a potential application is to use knowledge of anticipated congestion at stations (from passenger tracking) to encourage users to travel via another route or at another time ([Transport for London, 2017](#)).

Although these NEDF have been instrumental in encouraging positive travel choice change through better understanding of travel patterns, there is a need for more research into whether (and if so, how) these data forms can be used to directly and actively influence travel choice and behavior. Furthermore, there is currently a paucity of research into whether these NEDFs are causing travel behavior change, as opposed to merely facilitating it through allowing researchers and practitioners to have access to more varied datasets.

Data Challenges for Policy Makers

Missing Data and Bias in NEDF

Most NEDF are not primarily collected as mobility data and therefore they often suffer from biases and missing data, including people who are missing from the data entirely, and missing or inaccurate information on individual trips (or other variables, such as gender). Social media data, for example, has value for the transport sector ([Grant-Muller et al., 2015](#)) but may have been generated by a small number of “superusers” ([CEDR, 2017](#)). Whilst nearly 90% of the population of Europe currently have access to a mobile phone, the majority of which are smartphones ([GSMA, 2018](#)), not everyone has a mobile phone or uses it at the same rate. It is worth noting that smartphone location data refers to the movement of the device, which may be independent of the movement of the phone owner or user. In most cases, however, research on NEDFs acknowledges bias in the data but does not account for it. This is problematic since sampling bias and a lack of demographic information are key barriers to the wider use of NEDFs by practitioners and policy makers ([Lee et al., 2016](#)).

Many traditional data collection activities such as household travel surveys are designed to ensure (or at least aim for) area coverage and general population representation. While representation has been increasingly difficult to achieve ([Bonnell et al., 2015](#)), many new data sources (such as Strava Metro data, travel times and speeds from Uber Movement, or event data sourced through Twitter) may be more specifically limited to certain segments of the population. Consequently there is a risk of a biased or incomplete data picture if used to infer beyond their original context. This is especially problematic in policy making if it is to be holistic and equitable. The representativeness of the population covered by NEDFs varies across data types and may depend on app use (e.g., Instagram, Twitter) or device usage (e.g., mobile phone, desktop) which varies across age groups and socioeconomic groups ([Ofcom, 2019](#)). Providing wearable GPS devices to all participants can help to reduce the risk of bias associated with smartphone ownership ([Rasmussen et al., 2015](#)), and app usage, although the devices can be challenging to use for some older people ([Schmidt et al., 2019](#)).

Other issues relate to:

- Missing trip characteristics such as trip purpose or mode.
- With repurposed data the variables that are generated in the dataset cannot be determined by the end users.
- In combining new data sources to enhance modeling, careful attention must be paid to the ways in which data are linked and any underlying biases or errors that may be propagated.

Many areas, therefore, require further research, but the most pressing matter is likely to be the lack of sociodemographic information. Without this information it is not possible to identify which social categories and population segments are missing from the data or even attempt to address biases.

Complementarity between NEDF and Traditional Mobility Data and Modeling

In the short and medium term, the use of NEDF to augment traditional data sources by reducing known biases should be explored (Misra et al., 2014) and an effective way to utilize NEDFs in the future is likely to involve combining multiple forms of data. This approach creates added value from the differing attributes each source may have. For example, supplementing or replacing bespoke instruments for Household Travel Surveys with data collected through other means shows great promise for the transport sector. In such cases, the complementary use of different sources has the potential to add important information for under-represented groups (Birkin, 2018) and missing variables. Conversely, survey data can directly capture important behavioral information of a small sample, while emerging data sources can provide continuous mobility observations (Kusakabe and Asakura, 2014).

Even where it is not possible to link data on the same individuals in different datasets, the new forms of data may provide important small-area geospatial information to enhance existing individual-level datasets. Data fusion techniques can be applied with different independent sources of information to provide a better estimate of the parameters included in the system analyzed (Zhao et al., 2015). CDRs are one type of new mobility data form from a wider group of large-scale mobility data. Social network data provides a further opportunity to enrich mobility data. Shared similarities in mobility patterns, objectives, and mode choices serve as an input to optimal transport design and sustainable transport policy.

The integration of new data sources with main stream modeling does not necessarily imply that methodological barriers exist. An example where integration has taken place is the fusion of aggregate census data and disaggregate mobility data from sensors using an agent-based modeling framework, specifically an integral part known as population synthesis (Beckman et al., 1996). The result of that process is to obtain individuals with added semantic information important for policy-oriented transport modeling but previously only included at aggregate level in the census. This is coupled with high-resolution spatio-temporal mobility information from the raw sensing data. For examples see Wu et al. (2014) and Ali et al. (2016).

Skills and Engagement

Despite the wide policy implications of NEDF research and an increased willingness for data owners to consider how NEDF could be used for policy, a lack of sufficient academic engagement with policy-makers can be a barrier to their application (Marsden and Reardon, 2017). Most of the skills needed to optimize the use of NEDF are currently focused in academia, whilst stakeholders also need to identify other resources required to realize the data potential. Thus, a key gap is directing sufficient energy to responding to policy needs and disseminating the policy implications of research on NEDF to inform decision-making.

Emerging datasets in the form of unstructured data, such as textual (e.g., from social media) or video (from CCTV cameras in the road network) require different analysis tools. Text analytics is gaining in popularity as social media usage increases. Specifically, Natural Language Processing, a text analytics set of algorithms, provides the ability to summaries important latent semantic information in a specific text. Video analytics, on the other hand, can be carried out in an automatic way with the use of image processing techniques, such as convolutional neural networks.

In summary, the opportunities provided by new data have resulted in the development and adoption of new methods into transport modeling and policy-making. Most of the new skills required originate in fields outside transport, including statistics, computer science, economics and epidemiology, but these experts lack the necessary theoretical or policy background. The transition period for both groups can be challenging, but of paramount importance for the successful cooperation between them.

Other implications include:

- Data processing and model development costs may be higher due, for example, to data cleaning issues or lack of skills/resources.
- A challenge in leveraging the advantage of dynamism in the data lies in the ability to process and conduct computations in real time.
- The opportunity to further evolve transport models may give rise to methodological or skills-based challenges.

The Role of Data Ecosystems

When considering the use of new forms of data for sustainable transport policy, it is critical to address issues arising from the ecosystem of data collection, access, sharing, use, and archiving. Practices associated with these considerations will vary depending on a number of factors, including the status of the collecting agency (public, private, or third-sector), the type of data being collected, the sensitivity of the relevant data attributes (for example, are the data considered “personal” under the EUs GDPR), and their intended uses and users. As data resources continue to evolve, it will be necessary to ensure that the practices being followed in their use are compatible with legal and regulatory requirements; acceptable from a societal standpoint; adequately and accurately recorded; and future-proofed for ongoing value.

Collection and Access

Many traditional data collection activities are conducted in-house or via contractual agreements, with the contracting organization having a degree of agency over both the attributes and format of data collected. In the emerging mobility data ecosystem, however, it is not uncommon for data to be obtained or purchased from third-party vendors or open data sources. In such instances, issues of data standardization, formatting, and the practices followed when collecting (including ethical considerations) may be of concern.

Obtaining consistent data over time may be particularly difficult. Ensuring that appropriate metadata is available will be necessary for incorporation of such data resources into current practices, to allow attributes to be accurately represented in the data ecosystem. An associated concern is data ownership, as commercial considerations may preclude the sharing of “raw” data in favor of data that have been aggregated or otherwise modified to both reduce the potential disclosure of sensitive data and maintain the value of such data in commercial applications.

Sharing, Use, and Privacy

While many new forms of mobility data have been posited for incorporation into transport modeling and planning processes, they may also be used for more immediate decision making on the part of travelers or transport service organizations. Twitter data, for example, has been explored for use in the identification of traffic events and disruptions (Gu et al., 2016) as well as information provision to the traveling public (Cottrill et al., 2017). Services and apps such as Waze, Google Maps, and Moovit, on the other hand, make use of crowd-sourced data (or volunteered geographic information – VGI) to provide real-time information on public transport routes and traffic conditions to travelers and decision makers (Attard et al., 2016).

Emerging privacy issues can affect the potential value of new forms of mobility data. For example, many new datasets (e.g., Strava, Twitter, etc.) provide location information that could be highly disclosive and contravene the GDPR. Research using CDR data has already demonstrated the uniqueness of mobility traces (De Montjoye et al., 2013). To safeguard their commercial interests as well as their users’ privacy, many third-party vendors have adopted new privacy controls and changed the characteristics of their data products. The changes seen in the granularity of Strava data products for example could happen to other new forms of mobility data in the near future. Constructive conversation and clear understanding about the value of these new data between researchers (planners) and third-party vendors are necessary to ensure the quality of data and its value. Research should also continue into methods to increase privacy whilst minimizing data loss, for example Gao et al. (2019).

Business Models

The largely innovation-driven emergence of micro-mobility modes has disrupted established governance practices and highlighted issues around the commodification of data. City stakeholders, commercial entities and the individual all have a claim to “rights” concerning the location data generated. The balancing of the “public good” alongside those rights and the commercial imperatives has become contentious. New data for mobility stimulate the development of new business models. New business models mean that there are opportunities to generate new value; however, the development of a new business model requires explicit choices about the value proposition and choices about the importance of relative values for groups of different users. A summary of the opportunities and challenges for NEDF in contributing to sustainable policy at broad level is provided in Table 1.

Table 1 Opportunities and challenges for NEDF in contributing to sustainable policy

<i>Sustainable transport policy objective</i>	<i>Opportunities</i>	<i>Challenges</i>
Economy	• New types of business models related to data ownership/generation may arise • Real-time calibration and analysis supports efficiency in smart networks, including improved travel times. • Opportunity to develop more cost-efficient cross-sectoral models • More cost-effective to obtain larger and longer-term datasets than traditional methods, especially if secondary data.	• Increased model development and policy appraisal costs as new skills and resources required • Maintenance costs of monitoring smart networks • Availability and costs of commodified data
Environment	• More finely grained understanding of travel behaviors can lead to the design of more efficient networks and better land-use • Combining with environmental sensor information can identify and monitor areas of high pollution • Real-time calibration and analysis can contribute to more reactive and resilient (future-proof) smart networks	• Energy and emissions associated with data generation, processing and storage
Social	• More reliable long-term data of larger groups of individuals • Data value propositions allow individuals ownership of their own data • Potential to develop policies that can influence individual travel choices • Potential to target specific segments / sub-groups	• Representativeness of the population and sample bias may accentuate hitherto neglected segments of the population • Lack of socio-demographic information • Raises issues of data governance, especially concerned with individual privacy

Summary of Opportunities and Challenges of Technology Enabled Data for Sustainable Transport Policy

In conclusion, whilst the data needs for sustainable transport policy are complex and differ from those of many other sectors, NEDF enable profound new insights into human choices around mobility. Whilst these new data forms bring new challenges, especially in terms of sharing and privacy, the value proposition for the various stakeholders involved is increasingly recognized. Given the cross-sectoral and re-purposed nature of many NEDF, the most significant challenge may be a closer working of policy decision-making bodies to capitalize on the potential that NEDF offer.

Introduction

Car sharing (CS) is an emerging mobility practice that emphasizes access to a vehicle over ownership. CS platforms allow users to rent vehicles on a self-service basis for short periods of time. The first viable CS platforms were established in Switzerland and Germany in the 1980s, after which similar attempts were made in dozens of urban contexts in North America and Europe. The earliest platforms were member-owned cooperatives, which were followed up by commercial [CS enterprises](#) starting in the mid-1990s and peer-to-peer (P2P) platforms in the 2010s.

The most common ways to differentiate between the various types of CS are based on business and operational models. CS is also part of the broader sharing economy and is one among many new forms of mobility that challenge the dominance of privately owned vehicles in contemporary transport behavior and planning. Although CS does not rely on radically new technologies, its novel use of existing technology has potentially broad implications with respect to mobility, urban development and the environment.

What is Car Sharing?

CS refers to the mobility practice whereby members of a platform have rental access to cars on a short-term self-service basis through a formal service provider or intermediary. A more in-depth understanding of this definition can be gained by considering the distinctions between (1) formal and informal car sharing, and (2) car sharing and other types of mobility that emphasize vehicle access over ownership.

First, people have been sharing cars for as long as cars have been around. Such informal types of CS can be as simple as friends or family members borrowing a car from one another. Scholarly analysis of CS focuses almost exclusively on the formal variety. “The distinctive criterion is whether a central service structure exists that coordinates the activities of multiple users of a car and whether any legal form of association exists that own the cars. In private car sharing, it is usual for one person to hold legal ownership rights to the car, and access to the car is organized in an informal way” (Truffer, 2003, p. 154).

Second, when asking what CS is, it is worthwhile to consider what CS is not. Most importantly, CS is often confused with other forms of shared mobility that emphasize vehicle access over ownership, namely ride sharing and ride sourcing. The clearest distinction is that CS offers access to a vehicle that is operated by the user whereas ride sharing and ride sourcing offer access, as a passenger, to a vehicle that is operated by someone else. The Shared Use Mobility Center provides the following definitions (Shared Use Mobility Center Sumc, 2015[SUMC], 2016, p. 5-8):

- Car sharing: “a service that provides members with access to an automobile for short-term—usually hourly—use”.
- Ride sourcing: “platforms to connect passengers with drivers who use personal, noncommercial, vehicles”.
- Ride sharing: “adding additional passengers to a preexisting trip...Unlike ride sourcing, ride sharing drivers are not ‘for-hire’”.

Some definitions of CS provide general descriptions of the practice but leave room for ambiguity with respect to these and other related types of mobility. For example, according to Shaheen et al. (1998, p. 35) “The principle of carsharing is simple: individuals gain the benefits of private cars without the costs and responsibilities of ownership.” While this description is true, it is more a normative commentary on CS rather than a definition. It, furthermore, includes other types of car use like vehicle leasing.

Definitions that are more specific are often a list of criteria; Millard-Ball (2005, p. 2-1) provided the following:

- An organized group of participants
- One or more shared vehicles

- A decentralized network of parking locations (“pods”) stationed close to homes, workplaces, and/or transit stations
- Usage booked in advance
- Rentals for short time periods (increments of one hour or less)
- Self-accessing vehicles

Given that the authors were writing about CS in North America during the 1990s and early 2000s, it should come as no surprise today that their criteria do not take into consideration newer forms of CS like P2P CS that do not conform to the parking station/pod model. The authors follow their list up by citing the State of Washington’s definition of CS as being the most concise and comprehensive:

“A membership program intended to offer an alternative to car ownership under which persons or entities that become members are permitted to use vehicles from a fleet on an hourly basis.” (Washington State Legislature, 2005)

While the Washington definition is a relatively good one, it leaves room to include traditional rental car services that often require time-consuming paperwork and verification procedures during vehicle pick-up. A key feature of modern formal CS is that it is self-service, meaning that a user can access a vehicle without interacting with another human being. Similarly, Frenken (2013, p. 9) defines CS as “a system that allows people to rent locally available cars at any time and for any duration”. While this is generally true, it leaves out important elements of CS like membership and self-service access.

An additional source of confusion is that in some markets, the UK in particular, CS is known as car clubs, whereas the term CS often refers to ride sharing, carpooling and ride sourcing (Millard-Ball, 2005, p 2-1; Shaheen et al., 2015).

It is likely that the definition of CS will have to be updated to keep up with advances in technological innovation. For example, user operation is one of the distinguishing characteristics of CS; if autonomous vehicle technology develops further and removes the need for a human operator, the boundaries between CS, ride-sourcing and ride-sharing begin to blur and will potentially disappear.

Types of Car Sharing

There are several types of CS. To understand this variety, one can differentiate platforms based on business model or operational model.

Types of CS by Business Model

Broadly speaking, business model can refer to the organization’s mission, or what Millard-Ball (2005) refer to as organizational form, of which there are three main types: for-profit, nonprofit, and cooperative. In practice, cooperatives are a subset of nonprofit as just about all cooperative platforms are nonprofit, but not all nonprofit platforms are cooperatives.

The largest CS platforms in the world are for-profit corporate ventures. Zipcar, for example, is a subsidiary of the Avis Budget group, a traditional rental car company. Similarly, Share Now is a joint venture of the German automobile manufacturers Daimler and BMW. Whereas profit-driven corporations have greater access to venture capital and incentive to expand, nonprofit platforms have greater access to support from governments or foundations (*ibid.*). Furthermore, nonprofit platforms tend to focus on limited geographic contexts, usually one city, which is more likely to engender familiarity and trust from local stakeholders (Brook, 2004).

CS business models can also refer to the relationship between the customer and the service provider. Here as well, there are three main types: business-to-consumer (B2C), business-to-business (B2B) and peer-to-peer (P2P). There could theoretically be a fourth consumer-to-business (C2B) category in which individuals could rent out their private vehicles to businesses and institutions, but this model is yet to take off. Although CS platforms across all three business models have embraced information and communication technology (ICT) to develop their service offerings, the P2P model relies more heavily on such technology to carry out transactions—without smartphones, P2P CS would be virtually impossible. These categories are not mutually exclusive—platforms often have a hybrid business model that offers both B2B and B2C services.

Types of CS by Operational Model

The other main typology for differentiating CS platforms is based on operational model, which refers to how the vehicles are used. Martin and Shaheen (2016) identify four types—roundtrip, one-way, peer-to-peer (P2P), and fractional ownership. It is worth noting at the outset that P2P platforms are unique in that they represent a distinct operational model as well as business model.

Round-trip, also known as traditional or station-based CS, requires that vehicles be picked up and dropped off at the same location. It is the most common and oldest type of CS platform and spans across all business models. Nonprofit and cooperative platforms are almost exclusively round-trip in nature. A CS station is effectively a parking space, or set thereof, that must be made available exclusively for a shared vehicle. Such stations must be easily accessible to users—they are typically located in densely populated mixed-use residential urban neighborhoods (Shaheen and Cohen, 2013, p. 14).

Users of one-way CS can pick up and drop off vehicles in different locations, usually within a limited geographic area. They are almost always but not exclusively “free-floating” platforms for which the pick-up and drop-off locations are any available legal parking space; some one-way platforms operate on a station to station basis (Shaheen et al., 2015, p. 525). Some of the earliest

attempts at formal CS in the 1970s like Procotip in Montpelier, and Witkar in Amsterdam were one-way platforms. These were short lived because of technical and organizational challenges. Current one-way platforms rely on relatively recent technologies like smartphones and GPS, that were not available in prior decades.

ICT innovations have also played a central role in the development of P2P CS which involves private automobile owners renting out their vehicles to other users. The CS platform operators provides a digital interface that facilitates transactions, for which they receive a share of rental costs. In a traditional P2P CS schemes, both the provider and the user are private individuals. [Stocker and Shaheen \(2017, p. 10\)](#) also site hybrid and marketplace CS platforms. With Hybrid P2P, traditional CS organizations supplement their own fleet by renting privately owned vehicles on a short-term basis from individuals or other third parties. Marketplace P2P functions similarly to traditional P2P but less standardization with respect to price, pick-up and drop-off procedures, and dispute resolution.

Other kinds of CS that are less common include the following ([Martin and Shaheen, 2016](#); [Shaheen and Cohen, 2018](#)):

- Fractional ownership, also known as fractional leasing, refers to multiple users subscribing to a fleet of vehicles owned by a third party.
- Institutional fleets are shared cars used by staff, students, and members of businesses, government bodies, universities, and similar organizations.
- Park and ride CS aims to solve the “first and last mile” problem associated with public transit outside of urban cores.
- Guest or visitor CS platforms targets users that are “away from home” or in-transit, often at sites such as holiday resorts and airports.
- Research pilots, which are not intended to be commercially viable

Impacts of Car Sharing

The first scholarly analyses of CS were pilot projects in the 1980s, such as Mobility Enterprise at Purdue University and STAR in San Francisco, that were testing the feasibility and potential impact of such services. As the number of CS services in Europe and North American increased over the next decade, especially economically viable ones, broader analyses of commercial offerings, public response, and overall impact became possible. Whereas the initial studies focused on individual service providers and case cities, as the CS industry matured, subsequent studies began to take into consideration industry-wide effects and lifecycle impacts of car sharing.

The impacts of CS are often measured by a multitude of environmental, economic and social indicators. Environmental impact, especially as it relates to GHG emissions and climate change, are the most studied and written about. The most common indicators used for determining the environmental impacts of CS are:

- Vehicle holding at the household level
- Vehicle miles traveled/Vehicle km traveled (VMT/VKT)
- GHG emissions
- Modal splits/relationship between CS and other modes of mobility

By the early 2000s, the CS market in North America and Europe underwent a period of maturity. There was a marked increase in the number of national and international commercial enterprises, as opposed to local cooperatives. The most notable of these were Zipcar, Car2go, DriveNow, and Sunfleet, all of which were either spearheaded by or eventually acquired by an incumbent automobile manufacturer or traditional car rental company. During this time, scholarly analysis of CS began to expand beyond individual programs and cities. [Martin et al. \(2010\)](#) carried out one of the first studies of CS that used survey data from a broad set of user participants ($N = 6281$) in the United States and Canada. The study found that car sharing removed between 9 and 13 vehicles from the road for each shared vehicle deployed—a total reduction of 90,000–130,000 vehicles.

Concurrently, a similarly broad study of CS in Europe, co-financed by the European Union and entitled “Momo car sharing”, was carried out using survey data from 84 CS service providers that operated a fleet of over 3500 vehicles, mostly in Germany. The study found that CS generally reduced the CO₂ emissions footprint of vehicles by 15–20% ([Loose, 2010](#)).

As the popularity of CS increased, and newer forms of CS (i.e., free floating and P2P platforms) emerged, larger studies supported the claim that even these new types of CS reduce carbon emissions. According to [Firnknorn and Müller \(2011\)](#) who studied the free-floating service car2go in Germany, 13.5% of a total 17,000 members were expected to reduce their car ownership, which corresponds to a net reduction of almost 2000 vehicles. The same study indicates that CS users emitted 53%–60% less CO₂ and that even when assuming the highest level of fuel consumption, car2go users could increase their VMT by 167% and maintain an overall reduction in CO₂ emissions.

Implications for Policy and Planning

From a policy perspective, how a practice such as car sharing can undergo formation and reformation in a manner that it can sustain itself needs to be understood and taken forward in policies and programs.

Car sharing has a vital spatial dimension. It requires not just the existence of users, but a geographic concentration of them as well. Spatial proximity to transit stops, high frequency of public transport services, walking/cycling infrastructure and to a great extent, restricted parking are essential material elements of car sharing. In municipal periphery, with lower concentrations of shared cars and users, car sharing becomes much less attractive. This suggests that in addition to requiring a sufficient number of users, car sharing is the type of innovation that is viable only when its users are located close to one another.

As with other forms of sharing, car sharing is predicated on reputation or trust in other users and the institution that governs the collective (Botsman, 2012). By allowing users to operate independently of one another, automobility has developed without the need for such trust. Car sharing necessarily makes the user more dependent on other users, not only temporally and spatially, but also with respect to how well they treat the car. This trust is often carried forward at the institutional level as well. Currently, the cooperative model strikes the perfect balance between alternative business model and institutional trustworthiness. If car sharing and other shared goods and services are to gain in popularity, there must be ample institutional trust or reputation that is capable of off-setting any suspicion or lack of trust users may have among one another.

Furthermore, for creating effective policies and solutions, it is essential to analyze the behavior of car sharing users across multiple life stages. This set of knowledge, on user variations, will offer the necessary tools with which the practice of car sharing can be upscaled to a mainstream or dominant mode of transport. The relationship between user and promoter circumstances and conditions is not static, but coevolutionary. Promoters need to respond to how users actually use their products and services.

Additionally, government needs to engage in understanding the different retention and recruitment mechanisms at play and support the most effective mechanisms for car sharing. For example, rather than or in addition to using the language of cost savings, convenience and environmental sustainability to market car sharing, there is an opportunity frame car sharing as an integral part of an urban lifestyle which builds on neighborhoods created on the principle of accessibility by walking, bicycling and public transport.

Further Research

The current landscape of urban mobility is in a state of flux. Shared mobility is fast emerging as one of the most sustainable options to streamline daily mobilities. Car sharing, along with other shared modalities like bikesharing, E-scooters etc. need to be integrated in ongoing discussions on multimodality and Mobility-as-a-service (MaaS). Additionally, there is a need for broader long-term and multicontext studies to understand the temporal, geographic and demographic particularities of car sharing.

The impact of car sharing has been primarily assessed through changes in VKT and vehicle holdings. This is necessarily so because of the ease of plotting these standardized impacts to feed standardized assessments. But such research remain incomplete in multiple ways. First, they do not engage with quantifying noncarbon emissions like nitrous-oxide, carbon monoxide that are not associated with VKT as compared with carbon dioxide. The nexus between increased battery-electric shared cars and health implications needs further attention, as the levels of suspended particulate matter (SPM) which are a leading cause of respiratory harm among urban residents remain largely understudied in the context of car sharing (Uherek et al., 2010). Third, we lack knowledge on ways in which autonomous car sharing will compete with public transport in the future. The kind of business models needed to bring together these two modules together remains largely unexplored. Fourth, studies analyzing the impacts on landuse and urban form as a repercussion of increased shared mobility are needed. Finally, though the demographic effects have been partially analyzed, the cultural, social, and health implications (e.g., another pandemic like Covid-19 which brought the world to a standstill in 2020) of shared automobility in different contexts needs further examination. Furthermore, the interlocking of CS and the constructs of suburbanization, shopping malls, elderly homes, assisted living, business parks, special economic zones (SEZs), knowledge clusters, labor mobility, segregation, gentrification, conceptualizations of masculinity, trust, status, freedom, epidemic outbreaks and the general evolution of daily lives needs be further studied and discussed from different methodological, and disciplinary angles.

What is a Mega Transport Project?

Mega transport projects (MTPs) are described as large-scale physical assets, which may be linear (such as roads, railways, bridges, tunnels, waterways) or nodes (such as airports, ports, stations and their associated infrastructures) or a combination of these. MTPs can be standalone projects, or part of a program of projects, defined by a local, regional, or national strategy for example. In terms of “large scale” the classical literature defines MTPs according to their cost and size, although more recently we see a move toward using complexity and impacts as key elements in defining MTPs. It follows that most texts define MTPs according to one or more of four interrelated subcategories:

- **Cost:** definitions commonly specify a lower threshold for capital expenditure. For example, academic studies have adopted a minimum construction cost for MTPs of US\$1 billion (see Flyvbjerg et al., 2003; Hauswirth et al., 2004; Merrow, 1998; OMEGA, 2011; Priemus et al., 2008). Governments and commercial practice, in contrast, may adopt lower thresholds, such as in the UK, where large scale “National Infrastructure Projects” are those over £50 million pounds (IPA, 2016) or in Germany where Large Scale projects are classed as above €100 million Euro (Rothengatter, 2019). Classifications based on cost alone represent a proxy for a broader set of factors, for example the sheer size of budgets required for MTPs tends to require approval at the highest level, making them an inherently political decision. However, a threshold minimum value could be argued as rather arbitrary, as there are examples of nationally significant infrastructure projects which fall below these thresholds in countries with lower GDP and more modest transport budgets.
- **Complexity:** MTPs are often described as complex, given they are seldom single physical assets, but heterogenous combinations of hard infrastructure (physical and mechanical assets) and soft infrastructure (communication systems and the various institutions involved in their planning, delivery, and operation) which are packaged into a project to achieve a given set of objectives. Complexity here can refer to the state arising due to the interaction and feedback between these various subprojects and their stakeholders (internal complexity). However, the interdependencies between the project and its multidimensional contexts can also be wide-ranging and complex, giving rise to manifold uncertainties and risk throughout the project lifecycle, including inadequate, unreliable or misleading information; and conflicts between decision making, policy, and planning (Flyvbjerg, 2007).
- **Size:** MTPs are usually physically large, extending over long distances or large surface areas. For example, Phase 1 of the High Speed 2 railway currently under construction in the UK will run on 140 miles of dedicated track, and will require the acquisition of 70 km² of land, equivalent in surface areas to a medium size town (NAO, 2018). It follows that they are resource intensive undertakings, both in materials they consume, and the labor needed for their construction. They also have long planning and implementation horizons, often measured in decades and with target life expectancies of between 50 and 100 years. These unusually large spatial and temporal dimensions are important as they can result in significant nonhomogenous impacts distributed across geographies and economies, both intended and unintended, and with the subsequent production of project “winners” and “losers” (OMEGA Centre, 2011).
- **Impacts:** MTPs are undertaken by their promoters in the belief they will have transformational outcomes or impacts, via concentration–distribution type models (Sturup and Low, 2019). For example, MTPs are frequently perceived as critical to the “success” of major urban, metropolitan, regional, and/or national development because of their potential to affect significant socio-economic and territorial change (OMEGA Centre, 2011, 2012). It is argued that it is these impacts which set MTPs aside from conventional projects. MTPs shouldn’t be considered merely as larger and more expensive versions of traditional transport infrastructure investments. Rather, they should be regarded as a totally “different breed” of project (Capka, 2004) because of their diverse outcomes and impacts that frequently go well beyond the physical assets that are being delivered. However, the ability of MTPs to bring about positive socio-economic impacts can be contentious, for example there is limited evidence to support the

development of high-speed lines as a means for rebalancing economies or “leveling up” (Tomaney and Marques, 2013). MTPs can also bring about unintended consequences, such as increasing social inequity (Lee, 2018), uncertainties surrounding CO₂ emissions and ecological impacts (Cornet et al., 2018) and encourage procurement practices against the public interest (OMEGA Centre, 2011). Essentially, MTP can yield significant effects across the social, economic, technical, political, legal, and environmental domains. In this regard an important distinction must be made between project outputs, outcomes and impacts (Turner and Zolin, 2012) where outputs are the manifestation of the physical asset at construction closeout (e.g., completion of new road/rail bridge with three river crossings), outcomes are the direct effect of the output, say during the first few months/years of operation (e.g., increased passenger flows between A + B), and impacts are the longer term effects of the project output and outcome (e.g., reconfiguration of urban space and socio economic profile). It is also important to stress outputs/outcomes and impacts fall across a range of stakeholders who they affect in different ways at different times (Fahri et al., 2015).

MTPs have in recent decades rapidly grown in number, size, complexity, and cost. The increasing demand for MTPs is variously cited as driven by: the need to renew existing major assets as they come to the end of their life (Söderlund et al., 2017); high level economic objectives, such as distribution and leveling up (Tomaney and Marques, 2013; Institute for Government, 2019); forces of global competition and the “Great War of Independence on Space” (Castells, 1996); the necessity for counter cyclical investment (UN, 2009); technological showcasing (Frick, 2008); sustainable development (Cornet et al., 2018); and even national prestige (SMEC, 2001). It follows that MTPs currently feature as significant aspects in many of the development agendas worldwide and they are highly politicized, indeed, of all the factors impacting success and failure, studies cited the role of politics as a key driver (OMEGA Centre, 2012).

However, MTPs are also much quoted as “paradoxical” in nature (Arena and Molloy, 2010; Flyvbjerg et al., 2003; Jennings, 2012; Samset and Volden, 2016). In particular because, despite their seemingly ever-increasing popularity, they are consistently deemed “unsuccessful” because of their failure to meet their original expectations in terms of delivery outcomes, typically in terms of outturn cost, on-time delivery and specification. Arguments based upon these metrics have tended to dominate the international narrative about project success (see Morris and Hough, 1987; Flyvbjerg et al., 2003; Samset, 2012). Whilst more recently there have been attempts to also emphasize positive outcomes to balance the somewhat negative perspective of project performance (Rothengatter, 2019) these are in the minority.

What are the Typical Performance Issues During MTP Delivery?

Inspired by the MTP paradoxes, significant research has been undertaken to both identify explanations of MTP performance and to suggested solutions. MTP development, common with most infrastructure types, comprises a series of phases or steps, starting with project conception, through planning, appraisal, funding, delivery, operation and decommissioning, or renewal. Research to date has tended to focus on the earlier phases of this lifecycle, with some of the most well-known and influential, for example, studying the links between selected aspects of the planning and delivery phases, or “project front end”. Of these studies, Sanderson (2012) identifies three explanation types for megaproject performance as follows:

- **Type 1: Strategic rent seeking behavior:** Project promoters pose vested interests in seeking to misrepresent nonviable projects by inflating benefits and reducing costs. This rent-seeking behavior goes unchecked because the incentives to produce deceptive and over-optimistic estimates of project viability are much stronger than the disincentives for doing so, leading to situations akin to the “survival of the un-fittest” (Flyvbjerg, 2009). Given the typically lengthy timescales involved with MTP development and realization, “there is a lack of proper accountability for project promoters, typically politicians, because they are often not in office when the actual viability of a project can be assessed” (Sanderson, 2012: 436). Essentially this explanation assumes project promoters are capable of accurate estimates of viability, but these are not in their interests to produce as they expose the inefficiencies of their invested project. Resolutions of these issues include the legal requirement for risk analysis, the de-politization of the early decision-making phases, and policies aimed at increasing accountability (Davidson and Huot, 1989; Wachs, 1989; Flyvbjerg et al., 2002, 2003, 2005; Flyvbjerg, 2009).
- **Type 2: misaligned and under-developed governance:** the core argument here is that megaprojects are by their very nature turbulent, and underperformance of many megaprojects is best explained by the presence of insufficient governance arrangements that cannot effectively respond to the turbulence caused by the myriad risks inevitably associated with these endeavors. Differently from type 1, here promoters lack the capacity and capability to perform. Researchers from this perspective suggest a need for a better grasp of project turbulence through the design of adequate project governance frameworks (Miller and Lessard, 2000; De Meyer et al., 2002; Miller and Hobbs, 2009; Morris, 2009; Winch, 2009).
- **Type 3: diverse project cultures and rationales:** here “megaprojects are typically characterized by multiple and diverse discourses, cultures and rationalities rather than by a singular, shared rationality as is assumed by more orthodox, technicist perspectives” (Sanderson, 2012: 437). This means that different actors understand the individual elements of project and there interaction and interdependencies with others in very different and competing ways. Here “performance problems are an almost inevitable result of the normal day-to-day practice of managers trying to cope with an organizational environment that is complex, ambiguous, and often highly conflictual” (Clegg et al., 2002; Pitsis et al., 2003; van Marrewijk et al., 2008). Solutions include “generic management processes associated with building trust, sense-making, organization learning, and building an appropriate organizational culture” (Atkinson et al., 2006: 688).

Lehtonen (2019) terms these perspectives as those of the “mainstream rationalists” who seek to solve the presumed chronic problems of MTPs through calls for greater accountability, rigorous and independent ex-ante evaluation, and more effective ex-post monitoring and enforcement designed to minimize strategic, self-interested behavior. However, this research is far from conclusive, with Pitsis et al. (2018) amongst others identifying a broad range of further work to be done within this sphere.

The Strategic Success Paradoxes

There is potentially also another set of paradoxes, this time concerning strategic project success (OMEGA, 2012). There is a dearth of broader understandings and definitions of success beyond solely the narrow “iron triangle” metrics within which to frame and understand project performance against long-term impacts (OMEGA, 2012; Rothengatter, 2019). In particular, there are fundamental questions about what kinds of root problems MTPs are trying to solve, and if embarking on large scale, nonreversible, supply side physical infrastructure projects is always the best way forward in a world of fast behavioral change and rapid onset of disruptive technologies? There are questions regarding the ultimate outcome of the projects – how far do these go in solving some of the major problems facing society? (Fahri et al., 2015; Lehtonen, 2019; OMEGA, 2011; Söderlund et al., 2017; Samset and Voldon, 2016).

The very low rates of ex-post project evaluation mean projects continue to be developed despite a lack of rigorously validated understandings of their wide-ranging impacts, and tangible contributions to society. Whilst one of the challenges to establishing the success of a project can be attributed to “conditional causality” (Li, 2008) which can obscure the relationship between project outputs and outcomes, there is a well-established body of literature presenting methods of evaluation (Vanday, 2012) which can be adapted for application to MTPs. However, there remain few examples in the public domain of post project evaluations of MTP that go beyond time/cost/specification and economic assessments of project performance. The lack of evaluation has prevented practice from establishing widely accepted frameworks and procedures for broader evaluations, or for normalizing the routine collection of information required to fuel such evaluations. These oversights have limited our ability to more fully understand long-term impacts.

Lehtonen defines the few researchers responding to these issues as the “alternative approach” literature. These studies “emphasize the need for learning and reflexivity, as well as the complexity and dynamism of megaprojects” (Lehtonen, 2019:149). Here there is the more complex and intractable set of issues regarding project success against long-term project outcomes and impacts. Classic examples of this are Sydney Cross Harbor Tunnel (Turner and Zolin, 2012) or Highspeed 2, an HSR current under construction in the UK. These issues are typically broad, long ranging, complex, and interdependent.

Whereas the literature concerning the operational phases and their relationship with MTP success is both copious and tightly defined within the realm of project management and associated disciplines, the research concerning the success of MTP projects in terms of their outcomes and impacts is more sparse and spread across many disciplines. Below we bring together some the various strands of research as they relate to the blocking and inducement mechanisms to understanding more about long-term MTP project impacts and success.

MTPs as Interdependent and Open “System of Systems”

Some authors present a case for the need of more “open-systems” approaches to decision-making than current planning paradigms typically permit. There is a strand of literature which conceives MTP projects as “exploratory”, almost “organic”, allowing for unexpected outcomes to become recognized and accepted as part of an “emergent order”, replacing in some instances more planned orders (see OMEGA Centre, 2011). The two-way relationship between MTP decision-making and the external policy environment not only has these projects responding to economic and political changes over time, but also has them frequently acting as catalysts for major transformational change either by design or default. A important text underpinning such broader definitions of project success is “Planning as Wicked Problems”, from public policy research, which established that planning in general, and hence MTP decision making and development in particular, are beset by interdependent challenges of complexity, ambiguity, conflict, attenuation and knowledge, and institutional silos, amongst others (Rittel and Webber, 1973), and the metrics of success are “better” or “worse” rather than deterministic.

This contrasts with the observed tendency for MTPs to be planned and executed somewhat within their modal silos (Rosenberg et al., 2014). This can also be true of the guiding policy frameworks and institutions, which identify their need. For example, the UK’s National Policy Statements (NPS) or the projects identified by the National Infrastructure Plan together identify infrastructure investment going forward, but as such neither provides a complete joined up, systemic and strategic definition of infrastructure need. Indeed, many of the sector-specific NPS are badly out of date. The literature on the management of portfolios of projects encourages the consideration of project interdependencies beyond departmental silos (Hall et al., 2016; Young and Hall, 2015), and thus offers a step toward reconciling this situation. However this strand of research is currently sparse, leading to the open-systems and “wicked” nature of MTPs being commonly overlooked. This means their strategic influence, interdependency relationships with other infrastructure projects and associate developments, plus long term and operational phases can be somewhat neglected in decision making, limiting the ability to plan and control such impacts over the longer term.

Path-Dependent Appraisal Methods and Narrow Consideration of Impacts?

A common theme in the literature focuses on the inadequacies (and inappropriate applications) of *ex-ante* project appraisal methodologies negatively contributing to excessively narrow frames of project appraisal (see in particular, Dimitriou, 2009;

Macharis and Nijkamp, 2013; OMEGA, 2012; Schutte, 2010). Reinforcing this critique, there is also a growing body of literature expressing concern regarding the excessive importance given during project appraisal to overtly economic tools such as Cost Benefit Analysis (CBA) (see Alexander, 2006; Brown et al., 2001; Metz, 2008; Nss, 2006; as well as the exclusion of many project stakeholders from the planning and appraisal process (see Colomb, 2010; Haezendonck, 2007; Macharis and Bernardini, 2015; Macharis et al., 2009).

Authors of this body of literature have emphasized the need to ensure more holistic and transparent assessment of project proposals by employing methodologies such as Multi-Criteria Analysis (MCA) more extensively and increasing the participatory character of the appraisal exercise (see for example, Ward et al., 2016). This is seen as not only potentially enhancing sustainable development attributes in the evaluation of such mega projects but also better linking their policy and planning aims with their performance, when compared with measurement by more traditional metrics of project appraisal that focus on traditional narrow “iron triangle” delivery metrics discussed above. Whilst forms of MCA have been routinely applied to the planning of MTPs, such as via the Web TAG methodology (DfT, 2019), or even the airport commissions study on Airport Capacity to inform policy (Airports Commission, 2015) there is little evidence of such appraisal frameworks over-riding the outcomes of CBA.

Furthermore, whilst MTPs are traditionally funded by the public sector, the ongoing constraints on public budgets mean Public Private Partnerships (PPPs) are growing in importance globally as the favored procurement route. Some see the practicalities of PPPs as placing them at odds with aspirations for more inclusive and open project appraisal with adequate consideration of the public interest (see Shaoul et al., 2006; Siemiatycki, 2009).

Evaluation of Sustainable Development Goals (SDG) Remains Under-Developed

When we consider the intended outcomes and impacts of MTPs, traditionally, the underlying rationale of many MTPs, especially from the perspective of the State, has been the delivery of economic growth on the basis of the economic benefits they are predicted to generate or support (often measured through travel time savings). But it is well known that there are potentially significant environmental costs associated with these developments across all scales from local to global (Sturup and Low, 2019). Whilst MTPs remain developed and operated via fossil fuel there will be significant greenhouse gas emissions (Cornet et al., 2018). Gellert and Lynch (2003) highlight MTPs often cause displacement (either biophysical or social) both directly, such as habitat loss or eviction, and indirectly such as aquifer damage causing knock-on effects, or loss of access to resources. The creation of waste products from MTPs can also create issues of environmental injustice (Agyeman et al., 2002). MTPs furthermore can dramatically change local environments, causing severance and damage social cohesion (Lee, 2018). They can exacerbate equity issues, and they are frequently opposed by people living in their shadow. Sturup and Low (2019) highlight that undesirable social and environmental lifestyle habits can be locked in by the long life of MTPs which then become barriers to sustainable development (SD).

Of late, the emphasis on economic growth has been challenged by a broader agenda of multiple development aims in support of declared United Nations (UN) visions of sustainable development. These visions potentially re-define the order of development priorities that MTPs should contribute to, and even question the fundamental viability of MTPs. The Brundtland Report's (UN, 1987) definition of sustainable development implies an important shift from sustainability as a primarily ecological concept to a framework that also emphasizes the economic and social dimensions of development. The report underlines the belief that sustainable development is not just a matter of balance between its sometimes conflicting social, environmental, economic, and institutional dimensions, but also reflective of a need to respect the ecological limits of development as far as they are known (Rees and Wackernagel, 1994). When trying to apply concepts of sustainable development to MTPs it becomes clear that establishing measurable criteria across all domains of what is still a contested concept raises numerous challenges not least on how to combine a set of disaggregated criteria to represent “sustainability”. There can also be considerable time lag between identification and practical application of such concepts and criteria: an evaluation of the performance of 30 contemporary MTPs against SDG principles found very low adherence to SDG, mainly due to the projects having been conceived or constructed before SDG were integrated into decision making (Ward and Skayannis, 2019). Furthermore, whilst Environmental Impact Assessment (EIA) has become a mandatory aspect of many MTP developments, it's coverage of sustainability is only partial (Bruhn-Tysk and Eklund, 2002) and Social Impact Assessment, which offers further coverage of sustainability, is generally under applied (Vancley, 2017). Other examples of tools to introduce elements of sustainable development applied to MTP include DfT's Web TAG or the Asian Development Bank's STAR framework, developed by the bank to monitor progress in its investments toward supporting accessible, safe, environmentally friendly, and affordable transport (Véron-Okamoto and Sakamoto, 2014). However, whilst these tools are applied ex-ante, they are seldom deployed ex-post as tools evaluate project success against SD derived goals, and to arrive at a consistent outcome. Even when applied ex-ante, there are questions regarding the consistency of decision making outcome and the priority of information obtained via current SD appraisal tools, as illustrated by the recent successful legal challenge to the Heathrow Second Runway due to the failure to recognize commitments to climate change targets in consenting documents (Court of Appeal, 2020) suggesting key climate change policy was side-lined from core decision making and consenting processes.

Participation Practices Need “Opening Up” to Identify and Mediate Conflicts Over Impacts

The stakeholder theory literature often categorizes stakeholders by into two types, such as primary and secondary (Clarkson, 1995) where primary stakeholders are those with a direct involvement in, or impact on, the outcome of the project

(determined via power, legitimacy and urgency criteria) such as suppliers, government departments, etc., and secondary are those with less immediate impacts on projects such as community groups, lobbyists, environmental groups, etc., Whilst the literature highlights the importance of effective and early engagement with key stakeholders is seen as critical, and this has been mirrored in legislation in many countries (McAdam et al., 2010), the main stream rationalist literature has tended to focus on primary stakeholders. Whilst the consideration of secondary stakeholders and the impacts that fall upon them have been relatively under-researched “little is known about how to align project objectives with those of the secondary stakeholders” (Maddaloni and Davis, 2018:544). This shortfall in consideration for secondary stakeholders is therefore significant when considering the success of an MTP in terms of impacts.

The driver for stakeholder consultation is usually a need to avoid conflict, stemming from the unsuccessful Decide, Act, Defend (DAD) strategy of defending technocratically determined projects via the public arena (Beierle and Cayford, 2001). However, recent modes of participation have their own drawbacks. “Unless the nature of the consultation is so thorough and proactive as to obviate the need for conflict in the first place, we see consultation as affording opposition groups another opportunity to protest” (McAdam et al., 2010 p407). Critically, thorough and proactive consultation can result in the “opening up” of the infrastructure planning and design process to a plurality of new stakeholders to identify a broader set of potential risks and opportunities, and to reduce the premature discarding of options, perhaps of a more sustainable nature (Steinemann, 2001; Stirling, 2008) due to agency agendas, path dependent behaviors (Hellström et al., 2013) and solution templating.

Importantly, early consideration of these differing viewpoints allows the project to be scoped and specified appropriately from the outset (Rosenberg et al., 2014). Reducing the use of “straw men” or project alternatives predesigned to be rejected by the process. Problem definitions may furthermore be less than rigorously identified, leading to proposals treating symptoms rather than causes and structural outcomes. Issues also arise concerning the lack of meaningful public involvement in the decision-making process, with this involvement usually coming too late to influence the development of alternatives (Adelle and Weiland, 2012; Ward and Skayannis, 2019).

It should be appreciated that it also ensures an adequate redundancy of information is provided which is inevitably necessary when involving multiple different stakeholder groups in dynamic complex decision-making (Rosenberg et al., 2014). While the identification of the relevant actors and the analysis of their mutual relationships and agendas can be very challenging and lengthen the decision-making process, this advocated “opening up” to a plurality of voices and lines of argument makes for more effective consultation and is more likely to capture key issues that need to be addressed. This is also important given the traditional Planning regimes are adversarial in nature (Rydin et al., 2018).

Conclusions – Breaking the Paradoxes?

This article has sought to achieve three goals: the first is a common definition of MTPs, the second to review a selection of literature regarding causes and solutions for the MTP output or delivery performance paradoxes and the third to discuss a further set of MTP paradoxes, where MTP performance against project outcomes and impacts remains systematically unevaluated despite enormous investments which have been made, and continue to be made in such projects.

With regards to a common definition of MTPs, this article has discussed four fundamental criteria which have been repeatedly used in the literature to define them. What is clear is that definitions of MTPs remain generic and general, suggesting these have yet to merge into a mature body of knowledge.

The research driven performance paradox seeks to understand why MTPs consistently “fail” when measured against delivery performance “Iron Triangle” metrics (budget, schedule, and specification). Whilst the iron triangle of project management was conceived as a tool to represent trade-offs between these three features, they have become uncoupled, independent metrics to measure success. The literature finds numerous explanations for delivery failure against these metrics and offers various solutions which have been categorized here under three schools of thought. However, despite these efforts there is little evidence of the various prescriptions converting into empirically observed improvement in performance. Evaluation of project management intervention appears distinctly lacking from within the field. This suggests research is required to not only diagnose the various problems with MTP development, but to shed light on why the various prescribed solutions are not translating into greater success in delivery practice.

In terms of further strategic paradoxes this article suggests that promoters and governments continue to invest in these projects without firm evidence that their long term outcomes and impacts are likely to be as expected. In fact, many rationales driving investment transpire as highly contestable. In these terms, the challenge to MTP decision-making becomes more demanding: the first challenge of how to overcome the irreducible complexity and uncertainty which characterizes the decision-making for such large-scale infrastructures remains, but it is enveloped by questions around how to effectively shape them, so that they achieve their expected impacts for society and then to be able to capture their performance against these expected impacts. What is clear is ex-post evaluation frameworks remain narrow, under-developed, and chronically under applied so lesson learning does not happen to the degree that many government guidance documents would require or expect, and this issue is magnified with respect to the difficulties in incorporating dimensions of sustainable development and stakeholder participation into both appraisal and evaluation. Authors suggest a holistic appraisal methodology would do much to address many important issues surrounding project impacts that are all too often sidelined by a “business as usual” mentality, however, as this article highlights there is a significant lack of validated, empirically derived data with which to populate such frameworks.

Introduction

Transport planning refers to the processes of decision-making that shape the future of transport systems at local, regional, national, and international scales. A decision-making process is inevitably a process of choice. The outcome of transport planning will thus always favor certain concerns over others, certain investments over others, certain transport modes over others, certain areas over others, and so on – and, therefore, certain people over others. Transport planning is thus inescapably a normative activity that raises, or should raise, equity concerns.

This obvious understanding has not always been explicitly acknowledged. In the early days of the field, the late 1950s and the 1960s, transport planning was typically seen as a largely technical issue, an issue to be left to transport engineers who were to design the best possible transport systems based on the latest knowledge and technologies. This vision was obviously not shared by all and the practice of transport planning, with its focus on catering for rapidly growing car ownership and use, was criticized by some from its very inception (e.g., Mumford, 1963 [1953]; Jacobs, 1961). Indeed, during the 1970s many streams of academic research developed that were highly critical of the emerging “modern” transport landscapes, of the power relations embedded in them, and of their uneven impacts on people (notably, the bodies of literature on gender and transport, spatial mismatch, space-time geography, and transport-related social exclusion). Despite its critical stance, much of this work did neither confront transport planning head-on nor provide clear directions for an improved practice. As a result, transport planning and equity have remained two worlds apart for much of the 20th century.

That has radically changed since the early 2000s. Building on the highly critical studies linking transport and social exclusion (Lucas, 2012), the literature on transport and equity has burgeoned and philosophies of social justice have started to invade transport writing (Verlinghieri and Schwanen, 2020). Studies have started to address transport planning more head-on from an equity perspective. Yet, there is still no general agreement on how to relate to “equity considerations” within the context of transport planning. Analyzing a range of arguments, three ways to look at the issue can be discerned. But before turning to these, it is essential to briefly reflect on the term equity.

Equity

The term equity directs the attention to what differently positioned people and population groups receive, experience, enjoy or suffer—and to the question what different people ought to receive, experience, or enjoy. Typically, three different dimensions of equity are distinguished: distribution (the benefits and burdens or “goods” and “bads” that people receive), recognition (the way people are being addressed and related to, as individuals and as members of a group), and representation (the ability of persons and groups to co-determine the decisions that shape their lives). While each of these are important for transport planning, in what follows I will focus primarily on the first dimension: the distribution of goods and bads. While this narrows down the understanding of equity, it is the topic of distribution that has received most attention in the transport literature and it is also this topic that requires most domain-specific knowledge. At the same time, such a narrow perspective on equity has been criticized and the scope of equity will therefore be expanded again towards the end of this chapter.

Equity understood as distribution encompasses a wide range of topics, as transport planning distributes a host of goods and bads, albeit often indirectly and often without aiming for a particular pattern of distribution across the population. A host of partly overlapping goods can be distinguished, including tangible goods like transport infrastructure (kilometers of roads, proximity to a train station) and more abstract goods like travel speeds or accessibility. Likewise, a broad range of “bads” are produced by transport

infrastructures and their use, including noise pollution, local air pollution, climate impacts, and safety risks. Over the past two decades, more and more studies have been published analyzing the distribution of these and other goods and bads related to transport (Lucas and Martens, 2019).

Many of these empirical studies do not tackle the issue of equity head-on. Often, studies equate disparities with inequalities and inequalities with inequities. These terms, however, have a distinct meaning. The terms differences, disparities, and inequalities are in its essence descriptive terms. The terms inequities and injustices, in turn, imply a normative judgment of these differences. Equity requires explicit normative judgment. It requires researchers and transport professionals alike to leave their comfort zone of technical knowledge and expertise to explicitly address questions of right and wrong. Studies mapping disparities thus do not directly address equity, even though they may be framed in the language of equity and even though such studies are likely to raise questions of equity.

The fact that equity, justice, and fairness are normative concepts does not imply that they are subjective or entirely personal concepts, that what is just or fair is in the eye of the beholder and is beyond rational debate. Rather the opposite is true (see Taylor 1985). It is no coincidence that the terms “justice” and “justification” are linguistically related – and are so in many languages. The relationship between the two terms suggests that what is just can be justified, while what is unjust cannot be justified. This does not imply that injustices are never justified in everyday life (unfortunately, quite the contrary is true), but it does suggest that any justification for an injustice is likely to be rejected after due consideration. This link between justice and justification underscores that equity, justice and fairness are not subjective but intersubjective notions.

Intersubjective agreement of what justice is or at least what it is not is strikingly high in a number of key policy domains (Jeekel and Martens, 2017). For instance, in most European and many non-European countries, there is broad support for health care systems based on a fundamental notion of solidarity, with solidarity implying that people ought to have equal access to a reasonable minimum of health care services irrespective of their ability to pay for these services. A comparable broad agreement exists about the free provision of basic education to children, irrespective of ability, income, gender, or race. The fact that there is broad agreement in these domains confirms that justice is not merely a matter of personal taste, but that people can come to a (rough) agreement about what constitutes justice in a particular domain of concern.

The field of transport planning stands out from other main domains of government intervention, not only because there is no agreement (yet) on what constitutes justice in this domain, but also because a debate on what might constitute justice in transport is virtually absent. In what follows, I turn to three possible perspectives on equity in transport planning. The description of these perspectives is intended to inform the debate about justice in transport which is so direly needed.

Equity as an Impact of Transport Planning

In the first perspective on equity and transport planning, the traditional approach to transport planning is largely accepted and equity is seen as an impact of planning decisions (e.g., Schweitzer and Valenzuela, 2004; and many others). The traditional approach views transport planning as “the field of government intervention that aims to ensure effective and efficient movement” (Shiftan et al., 2007). This understanding has gone hand in hand with a focus on the performance of the transport system, as a well-functioning transport system was and often still is seen as a precondition for ensuring “effective and efficient movement”. A well-functioning transport system, in turn, is typically equated with a congestion-free system. While this principle applies to both the road and public transport networks (and nowadays is even applied to bicycle network planning, for instance in the Netherlands), in practice it has implied a focus on solving congestion on road links.

This focus on congestion has shaped transport planning from its very start. It went hand in hand with the measurement of travel time losses and forecasting of time savings that may be generated by transport investments. Over the years, transport planning has slowly broadened its horizon to account more systematically for other impacts of transport investments, most notably environmental impacts and traffic safety implications. These concerns have affected transport planning to some extent, sometimes resulting in more environmentally-sensitive road planning, sometimes leading to a (limited) shift away from roads towards more sustainable modes of transport. Likewise, concerns over safety have led to better road design and – in some instances – to more priority for walking and cycling. More recently, there have been calls to also address the social consequences of transport planning. In most countries, however, congestion reduction has remained an overarching *raison-d’être* for transport planning.

At first glance, the increasing interest in equity adds an additional “impact” to this growing list of concerns. After all, equity can be seen as yet another concern to take into account when considering alternative transport futures. But at a closer look, equity actually adds an additional *dimension* to the analyses that need to be conducted within the context of transport planning. This is so because equity requires an understanding of the distribution of each benefit and cost over different population groups. When equity is taken seriously, it is no longer sufficient to analyze, for instance, the increase (or decrease) in air pollution due to a transport intervention. It is no longer sufficient to determine whether a project generates net benefits. Rather, it becomes necessary to analyze in detail *which* population groups benefit and which lose out. Moreover, in order to determine whether the expected distribution of impacts is fair, a normative judgment is essential, which in turn requires an explicit equity yardstick. Equity, even if understood as an impact, thus adds a layer of complexity to the traditional approach to transport planning.

This distributional concern is slowly entering policy making, although it is certainly not part and parcel of the standard practice of transport planning. Some major advances can be observed in the UK and the USA. In the UK, the national government introduced a requirement for a Social and Distributional Impact (SDI) appraisal of all new road projects over £10 million. First introduced in

2011, this requirement has since been updated and refined (Department for Transport, 2014). The purpose of SDI appraisal is to ensure that vulnerable population groups are not adversely affected by new projects (Martens and Lucas, 2018).

The SDI guidelines are to some extent similar to the requirements in the USA, where some major advances have been made in the analysis of equity impacts. The vast (economic) disparities between (ethnic) groups have triggered a high sensitivity for distributional issues in the USA, not in the least because of the influential environmental justice movement. This has resulted in a series of federal directives and guidelines requiring transport planning authorities to conduct equity analyses. These guidelines have indeed helped to shape practice, with an increasing number of metropolitan planning organizations and other authorities starting to conduct distributive analyses, first primarily regarding the burdens of transport and more recently also regarding the benefits (Karner and Niemeier, 2013). Given the lack of clear guidance on how to analyze and normatively assess equity impacts, it is no surprise that these analyses vary in multiple dimensions, including the benefits and burdens addressed, the population groups distinguished, the indicators used, and the (implicit or explicit) standards of justice employed. In many cases, transport planning bodies do not adopt any explicit equity principle to assess the results of the distributive analyses (Martens and Golub, 2018). In other cases, they adopt the principle of proportionality following legal requirements that public agencies identify and avoid “disproportionately high and adverse” effects on minorities and weaker communities (Schweitzer and Stephenson, 2007). The principle of proportionality requires that population groups receive a share of benefits or burdens that does not deviate too much from their share in the total population, leaving substantial flexibility to public authorities to determine whether observed distributive patterns are at odds with requirements of equity or not. Perhaps even more important is the lack of clarity in policy documents regarding the link between conducted distributive analyses and proposed interventions and policies. In many cases, the mapping of equity impacts seems to be conducted as an add-on that does little to change the primary concern in transport planning with congestion mitigation. The general impression is that as long as the impacts of proposed transport plans and projects are not blatantly disproportionate, distributive impacts have few implications for policy priorities (Lowe, 2014).

While the practices in the UK and the USA can be criticized on numerous grounds, it is also clear that other countries could learn from the experiences in analyzing a range of equity impacts related to transport plans and programs. At the same time, these experiences give little direction on how to weigh equity impacts vis-à-vis the many other impacts generated by transport interventions. Like negative externalities, attention for equity may ultimately do little to change the practice and priorities of traditional transport planning, as long as it is merely seen as an impact of transport planning.

Equity as a Goal of Transport Planning

The second perspective on transport planning and equity seeks to put transport planning on a par with other major domains of government intervention, such as health care, education and housing. Like transport, each of these domains is concerned with the delivery, broadly conceived, of a particular good to citizens. In contrast to transport, equity is not seen in these domains as a mere impact but rather as a key goal of government policies, with regulations, taxes and subsidies designed to deliver equity in each of the domains. For instance, many countries have enshrined a right to housing in their constitution and have set up extensive policy frameworks encompassing housing supply and demand measures with the purpose of providing adequate housing for all citizens. While in none of these domains there is complete agreement about what fairness exactly requires from government, there tends to be broad support for the core justice principles, among decision-makers, politicians and citizens, across a very large share of the political spectrum.

The second perspective on transport planning and equity takes the policy domains of health care, education, and housing as its model. This both broadens and narrows concerns over equity. It broadens these concerns, because equity now becomes an *objective* of transport planning rather than an impact. It narrows down the concerns, because this second perspective draws all attention to one key outcome of transport policies: accessibility. This focus does not imply that the (distribution of) the externalities related to transport are irrelevant. Rather, it is argued that these externalities, such as air and noise pollution, can be properly seen as impacts, while providing accessibility is the very purpose of transport systems—and thus should be treated differently from these impacts in the transport planning process.

The understanding that the provision of accessibility is the very purpose of transport planning goes back to at least the early 1970s, but has gained in strength since the 1990s, as symbolized by Cervero’s classic paper calling for a paradigm shift from (auto) mobility to accessibility (Cervero, 1997). The call for a focus on accessibility is based on the fundamental insight that travel is first and foremost a means to an end, a means to access destinations dispersed over space. Hence, many authors have argued that transport planning should not focus on the measurement and enhancement of mobility, but should rather analyze and enhance accessibility (Levine et al., 2019).

From the perspective of justice and fairness, accessibility does not merely represent the “service” people receive from the transport system. Rather, it captures the much more fundamental notions of choice and freedom. Accessibility, understood as the range of activities and destinations people can reach within a reasonable budget of time, costs, and effort, represents the choices available to persons. The higher a person’s accessibility level, the more destinations are available, the larger her freedom to choose from multiple options, and hence the broader the possibilities for the person to execute her agency and give direction to her life. Accessibility can thus be seen as a, perhaps rather technical, measure of freedom, with freedom understood in a positive rather than a negative way, that is, defined as “freedom to” rather than “freedom from” (Berlin, 1958). It is this understanding that makes the distribution of accessibility of particular importance from the perspective of justice.

The equity perspective adds a fundamental layer to transport planning's focus on accessibility. From an equity perspective, it is not sufficient to assess transport interventions based on the extent to which they enhance accessibility "in general" or "on average". Rather, it becomes key to determine how accessibility is distributed over different population groups and how proposed interventions are expected to change this pattern of distribution. Moreover, in order to assess the fairness of these (changes in) accessibility patterns, a normative assessment of accessibility patterns is required, based on an explicit equity yardstick or justice principle.

This raises the core question of this second perspective on transport planning and equity: What is a fair distribution of accessibility? A range of authors have grappled with this question in recent years (see [Verlinghieri and Schwanen, 2020](#)) and have explored the relevance and implications of a range of social justice philosophies for transport. The depth of the academic debate has been limited so far, as few authors have taken up the challenge of developing a systematic and robust defense of a particular principle. Moreover, a societal debate, so essential as part of any call for justice, is still largely absent. Partly because these debates remain underdeveloped, no broad agreement on a proper justice principle for the domain of transport has emerged yet ([Martens and Lucas, 2018](#)). Different authors have proposed different principles, including sufficientarian and more egalitarian principles. The former type of principles set a minimum standard in terms of accessibility ([Martens, 2017](#)). More egalitarian approaches might call for the adoption of a range constraint on accessibility, implying a maximum difference between persons with the highest and lowest level of accessibility (e.g., [Golub and Martens, 2014](#)).
